REFERENCE INDEX

Technical-Subject Index

Abnormal Voltage Conditions in Three-Phase Systems Produced by Single-Phase Switching. Clarke, Peterson, Light.....329–39; disc. 618
Accelerating Electric Motors Automatically, Two New Methods of. Leitch....487–93; disc. 655
Acceleration Tests on Large Synchronous Pump Motors, Some. Ager.........416–22; disc. 649
Accuracy of Three-Phase Metering Combinations, Relative. Weller...........925–9; disc. 1336
Additions to Power Systems, Superposition Methods for Calculating Effects of. Rettig...........................396–401; disc. 648
Air and of Freon in a Uniform Field at High Pressures, D-C Breakdown Strength of. Trump, Safford, Cloud...............132–5; disc. 676
Air at High Pressure, The Electric Strength of. Part II. Skilling, Brenner...112–115; disc. 677
Air-Blast Circuit Breaker for High-Voltage Service, A Conserved-Pressure. Rankin, Bennett.............................193–7; disc. 673
Air-Blast Circuit Breakers for Metal-Clad Switchgear, Medium-Capacity. Bennett, Wyman.............................383–8; disc. 627
Air-Blast Circuit Breakers, Mechanical Simplicity of. Haberl, Jensen........869–74; disc. 1355
Air Breaker, A Vertical-Flow Outdoor Compressed. Ludwig, Baker.............217–22; disc. 672
Air, Calculation of Initial Breakdown Voltages in. Ver Planck.........................99–104
Air Circuit Breaker With 250,000-Kva Interrupting Capacity, A New. Dickinson, Nau.............................197–201; disc. 671
Air Circuit Breakers in Cascade Arrangement, Protection of Low-Voltage Circuits by. Anderson, Black.................1151–60; disc. 1356
Aircraft Precipitation-Static Radio Interference. Starr...........................363–70
Alcoa Rectifier Installation. Housley, Winograd.............................1266–74; disc. 1409
A-C Arcs in Flowing Liquids, Photographic Study of. Slepian, Browne........823–8; disc. 1330
A-C Dielectric-Loss and Power-Factor Method for Field Investigation of Electrical Insulation, The. Doble..............934–9; disc. 1348
A-C Motor, Theory of the Brush-Shifting. Conrad, Zweig, Clarke.
  Part I...............................829–34
  Part II..............................834–36
A-C Network Calculator, The Modern. Parker.............................977–82; disc. 1395
A-C Pilot-Wire Relay, An Improved. Neher, McConnell..................12–17; disc. 638
A-C Power-Transmission Systems, Stability Limitations of Long-Distance. Clarke, Crary.............................1051–9; disc. 1299
A-C Secondary Network Systems, Modern Relaying for. Beeman..........237–41; disc. 683
A-C Systems, Short-Circuit Calculating Procedure for Low-Voltage. Darling...1121–36; disc. 1294
Altitude in the United States, Variations of Atmospheric Temperature With. Tenney.............................230–2; disc. 727
Ammeter, Automatic Printing. LeClair.............................93–9; disc. 757
Ampere Method of Designing Capacitor Motors, The Equal-Volt-. Trickey..990–2; disc. 1309
Ampere-Squared-Second Recorder. Rich...839–42
An Electrical Governor. Morgan...........80–4
Analysis, A Cathode-Ray Method of Wave. Johnson.................1032–6; disc. 1398
Analysis of Completely Transposed Multiconductor Transmission Lines, Transient. Pipes....................346–51; disc. 621
Analysis of Motor Temperature Rise, Complete. Felix, Jungk...............578–86; disc. 684
Analysis of Short-Circuit Oscillograms. Kuyper.............................151–3; disc. 752
Analysis of Transient and Sustained Voltages in Ground-Fault Neutralizer Systems, An. Farnham, Hunter, Peterson....1257–66; disc. 1394
Analytical Methods of Solving Discrete Nonlinear Problems in Electrical Engineering. Keller.................1194–1200; disc. 1389
Analyzer, A Turbine-Governor Performance. Osbon.........................963–7; disc. 1401
Analyzer for Determination of Circuit Recovery Characteristics, The Recovery-Voltage. Dunlap......................958–62; disc. 1391
Apparatus and Frequency-Control Possibilities, Short-Wave Diathermy. Gieringer....459–64
Apparatus Bushings, Report on. (Committee Report)........................266; disc. 695
Apparatus Flashover, Atmospheric Variations and. McAuley.................798–803; disc. 1319
Apparent-Impedance Method of Calculating Single-Phase Motor Performance, The. Morrill...........................1037–41
Appliances, Design Factors Involved in the Design of Domestic Motored. Packer...500–07; disc. 665
Application, Electric Locomotive. Brandenstein, MacLeod................1210–15; disc. 1382
Application of Electricity for the Auxiliaries of Railroad Trains, The. Gardner...34–6; disc. 632
Application of Ignitrons to Resistance-Welding Control, The. Bivens.......471–8; disc. 655
Applications, Classification and Co-ordination of Short-Time and Intermittent Ratings and. Hellmund.....................792–8; disc. 1323
Applications of Negative-Glow Lamps, Some Characteristics and. Ferree.......8–12; disc. 622
Arc-Backs in Ignitrons in Series. Slepian, Pakala.................................292–4
Arc Extinction, Displacement and Diffusion in Fluid-Flow. Slepian.........162–7; disc. 643
Arc Furnaces—Performance and Power Supply, Large Electric-. Jones, Stearns.............................763–9; disc. 1325
Arc Interruption, The Geometry of. Boehne.............................524–32; disc. 675
Arc-Over on Overhead Distribution Lines and Newly Developed Equipment for Protection Against Conductor Burndown From That Cause, Power. Matthews..596–604; disc. 684
Arc-Welding Generators and Transformers, The Service Factor Rating of. Freeman, Welch.............................137–41; disc. 726
Arcing Faults in Power Systems. Concordia, Peterson...................340–6; disc. 614
Arcs in Flowing Liquids, Photographic Study of A-C. Slepian, Browne......823–8; disc. 1330
Areas of Impulse Spark-Over, Volt-Time. Hagenguth...................803–10; disc. 1312
Armatures, Short Circuits in Synchronous-Machine. Galbraith...........................1024–9
Arrester Performance Characteristics, Line-Type Lightning-. Committee Report.........982–3
Arresters, The Protection of Solid Insulation by Lightning. MacCarthy, Carpenter.............................912–15; disc. 1349
Artificial Respiration, A Comparison of the Relative Efficiency of the Schafer and Pole-Top Methods of. Kouwenhoven, Hooker, Langworthy.......................41–4; disc. 660
Asynchronous Machine, Damping and Synchronizing Torque of the Double-Fed. Liwschitz..............................923–4
Atmospheric Temperature With Altitude in the United States, Variations of. Tenney.............................230–2; disc. 727
Atmospheric Variations and Apparatus Flashover. McAuley...............798–803; disc. 1319
Audio Frequencies, Power Circuit Instruments for the Higher Range of. Lunas, MacGahan..1230–5
Audio Noise of Transformers, The. Sealey.............................109–12; disc. 745
Automatic Printing Ammeter. LeClair.............................93–9; disc. 757
Automatic Telephone Networks, Rural. Ffolliott.............................1079–83; disc. 1304
Automatically Reclosing Breaker for Co-ordinating Distribution Systems, An. Rawlins, Wallace...........................1021–4
Automatically, Two New Methods of Accelerating Electric Motors. Leitch....487–93; disc. 655
Auxiliaries of Railroad Trains, The Application of Electricity for the. Gardner..34–6; disc. 632
Auxiliary Impedances in the Single-Phase Operation of Polyphase Induction Motors, The Use of. Ager....................494–9; disc. 660

B

Base-Load Stations, A New Transformer for. Sporn, Putman............916–18; disc. 1358
Basic Impulse Insulation Levels, Standard. (Committee Report)....................1448
Basic Principles of the Varioplex Telegraph. Holcomb..........................1102–08
(Basic Sciences) A Construction Theorem for Evaluating Operational Expressions Having a Finite Number of Different Roots. Cromwell.......................273–6; disc. 676
(Basic Sciences) A Five-Figure Table of the Bessel Function $I_n(x)$. Dwight..............135–6
(Basic Sciences) A New Method for Introducing Relaxed Initial Conditions in Transient Problems. Johnson.......................178–81
(Basic Sciences) A Short Method for Evaluating Determinants and Solving Systems of Linear Equations With Real or Complex Coefficients. Crout...........................1235–41
(Basic Sciences) An Experimental Investigation of Subharmonic Currents. McCrumm.............................533–40; disc. 722
(Basic Sciences) Analytical Methods of Solving Discrete Nonlinear Problems in Electrical Engineering. Keller........1194–1200; disc. 1389
(Basic Sciences) Calculation of Initial Breakdown Voltages in Air. Ver Planck.........99–104
(Basic Sciences) D-C Breakdown Strength of Air and of Freon in a Uniform Field at High Pressures. Trump, Safford, Cloud...132–5; disc. 676
(Basic Sciences) Diode Rectifying Circuits With Capacitance Filters. Waidelich.............................1161–7; disc. 1388
(Basic Sciences) Electric Strength of Air at High Pressure—II. Skilling, Brenner.............................112–15; disc. 677
(Basic Sciences) Formulas for the Inductance of Rectangular Tubular Conductors. Higgins.............................1046–50; disc. 1409
(Basic Sciences) High-Pressure Gas As a Dielectric. Nonken.................1017–20; disc. 1405
(Basic Sciences) High-Voltage D-C Flashover of Solid Insulators in Compressed Nitrogen. Trump, Andrias...........986–90; disc. 1393
(Basic Sciences) Linear Transformations in Three-Phase Circuits. Pipes.......351–6; disc. 619
(Basic Sciences) Measurements of Pre-Breakdown Currents in Dielectrics With a Cathode-Ray Tube. Race................854–8; disc. 1388
(Basic Sciences) The Dielectric Strength of Glass—an Engineering Viewpoint. Shand.............................814–18; disc. 1331
(Basic Sciences) Transient Analysis of Completely Transposed Multiconductor Transmission Lines. Pipes..............346–51; disc. 621
Basis for the Nondestructive Testing of Insulation, The. Field................890–5; disc. 1347
Batteries in the Transportation Field, Lead Storage. Whitehurst...........303–07; disc. 683
Bearings, Effect of Sapphire-Crystal Orientation on the Wear of Watt-Hour-Meter. Goss.............................811–14; disc. 1336
Behavior of Point Gaps at 60 Cycles. Lebacqs.............................44–8; disc. 651
Bessel Function $I_n(x)$, A Five-Figure Table of the. Dwight...........................135–6
Bibliography of Relay Literature—1927–1939. (Committee Report)...............1435–47
"Black Band" Method of Commutation Observation, The. Schroeder, Aydelott..446–51; disc. 659
Board of Directors, Report of the........1449–63
Body Currents, The Measurement of. Schwab.............................919–23
Braking Magnets for Watt-Hour Meters. Kinnard, Goss.....................431–9; disc. 653
(Breakdown) Measurements of Pre-Breakdown Currents in Dielectrics With a Cathode-Ray Tube. Race.....................854–8; disc. 1388
Breakdown Strength of Air and of Freon in a Uniform Field at High Pressures. Trump, Safford, Cloud..................132–5; disc. 676
Breakdown Voltages in Air, Calculation of Initial. Ver Planck.........................99–104
Breaker, A Vertical-Flow Outdoor Compressed-Air. Ludwig, Baker.............217–22; disc. 672
Breaker for Co-ordinating Distribution Systems, An Automatically Reclosing. Rawlins, Wallace.............................1021–4
Breaker for High-Voltage Service, A Conserved-Pressure Air-Blast Circuit. Rankin, Bennett.............................193–7; disc. 673
Breaker Ratings, Power-Circuit-. Van Sickle.............................882–4; disc. 1353
Breaker With 250,000-Kva Interrupting Capacity, A New Air Circuit. Dickinson, Nau.............................197–201; disc. 671
Breakers, Dielectric Strength of Oil for High-Voltage Testing of Oil Circuit. Lingal, Skeats, Braley...........................903–08
Breakers for Metal-Clad Switchgear, Medium-Capacity Air-Blast Circuit. Bennett, Wyman......................383–8; disc. 627
Breakers in Cascade Arrangement, Protection of Low-Voltage Circuits by Air Circuit. Anderson, Black...............1151–60; disc. 1356

Breakers, Mechanical Simplicity of Air-Blast Circuit. Haberl, Jensen......869–74; disc. 1355
Breakers, The Vertical-Flow Interrupter and Its Application to "Oil-Poor" Circuit. Baker..........................440–5; disc. 635
Broadcast Transmitter, A Push-Button-Tuned 50-Kw. Rockwell, Lepple...............1–3
Broadcasting in Canada, Radio. Frigon..........................896–8; disc. 1357
Broken-Delta-Secondary Transformer Circuits, Criteria for Neutral Stability of Wye-Grounded-Primary. Shott, Peterson..997–1002; disc. 1394
Brush-Shifting A-C Motor, Theory of the. Conrad, Zweig, Clarke.
  Part I..................................829–34
  Part II.................................834–36
Buffers by Electrical Means, Testing of Elevator. Kimberly.................................53–4
Bulb Mercury-Arc Rectifiers for Traction Service, Glass-. Woolgar...........843–6; disc. 1383
Burndown From That Cause, Power Arc-Over on Overhead Distribution Lines and Newly Developed Equipment for Protection Against Conductor. Matthews....596–604; disc. 684
Bus-Bar Electrical Distribution Systems for Industrial Plants, Enclosed. Carlson..........................297–302; disc. 700
Bus Differential Protection, New Current Transformer for. Kennedy, Sinks..1180–7; disc. 1363
Bus Protection Independent of Current-Transformer Characteristics. Steeb..859–62; disc. 1365
Bus Short-Circuit Protection, D-C Machine Flashover and. Montgomery, Sellers..........................1168–73; disc. 1370
Bushing and Associated Insulation Testing by the Power-Factor Method. Baltzly, Schlottere..........................308–12; disc. 744
Bushing Tests. Brownlee, Wickham..........................940–2; disc. 1344
Bushings Designed to Meet Modern Service, High-Voltage. Brandt, Rorden...255–60; disc. 696
Bushings, Report on Apparatus (Committee Report).......................266; disc. 695

C

Cable Design, A New Principle of. Del Mar..........................206–10; disc. 705
Cable, Picture Transmission by Submarine. Milnor......................105–08; disc. 756
Cable Quality, Impulse Strength as a Measure of. Komives.................929–34; disc. 1339
Calculating Effects of Additions to Power Systems, Superposition Methods for. Rettig..........................396–401; disc. 648
Calculating Procedure for Low-Voltage A-C Systems, Short-Circuit. Darling..........................1121–36; disc. 1294
Calculating Single-Phase Motor Performance, The Apparent-Impedance Method of. Morrill..........................1037–41
Calculation and Control by Capacitors, System Lower-Harmonic Voltages — Methods of. Feaster, Harder............1060–6; disc. 1310
Calculation of Initial Breakdown Voltages in Air. Ver Planck..........................99–104
Calculations on Capacitor Motors, Performance. Trickey.....................73–6; disc. 662
Calculations on Repulsion Motors, Performance. Trickey.....................67–73; dics. 661
Calculator, The Modern A-C Network. Parker..........................977–82; disc. 1395
Camera, A Cathode-Ray Oscillograph With Rotating-Drum. Downie..................984–6
Canada, Radiobroadcasting in. Frigon..........................896–8; disc. 1357
Capacitance Filters, Diode Rectifying Circuits With. Waidelich..........1161–7; disc. 1388
Capacitor Motor, The Cross-Field Theory of the. Puchstein, Lloyd............58–62; disc. 667
Capacitor Motors, Performance Calculations on. Trickey.....................73–6; disc. 662
Capacitor Motors, The Equal-Volt-Ampere Method of Designing. Trickey......990–2; disc. 1399
Capacitors and Circuit Performance. Butler..........................408–15; disc. 646
Capacitors, Self-Excitation of Induction Motors With Series. Wagner......1241–7; disc. 1391
Capacitors, System Lower-Harmonic Voltages—Methods of Calculation and Control by. Feaster, Harder...........1060–6; disc. 1310
Capacity, A New Air Circuit Breaker With 250,000-Kva-Interrupting. Dickinson, Nau..........................197–201; disc. 671
Capacity and Interconnections of the Columbia Gas and Electric Corporation, Increased. DeForest..............................451–8
Carrier Current Relay Channel to Other Uses, Possibilities and Methods of Extending a. Smith, Goldsborough.........23–7; disc. 645
Cascade Arrangement, Protection of Low-Voltage Circuits by Air Circuit Breakers in. Anderson, Black......................1151–60; disc. 1356
Cathode-Ray Method of Wave Analysis, A. Johnson...................1032–6; disc. 1398
Cathode-Ray Oscillograph With Rotating-Drum Camera, A. Downie..................984–6
Cathode-Ray Tube, Measurements of Pre-Breakdown Currents in Dielectrics With a. Race..........................854–8; disc. 1388
Cathode Tubes, Current Rating and Life of Cold-. Rockwood..............901–03; disc. 1390
Cellulose Insulation, Factors Influencing the Mechanical Strength of. Clark..778–83; disc. 1321
Channel to Other Uses, Possibilities and Methods of Extending a Carrier Current Relay. Smith, Goldsborough................23–7; disc. 645
Characteristics and Applications of Negative-Glow Lamps. Ferree..............8–12; disc. 622
Characteristics, Bus Protection Independent of Current-Transformer. Steeb...859–62; disc. 1365
Characteristics, Line-Type Lightning-Arrester Performance. Committee Report.........982–3
Characteristics of Driven Grounds, Impulse and 60-Cycle. Bellaschi.........123–8; disc. 717
Characteristics of Two-Winding Transformers, Surge. Rudenberg.......1136–44; disc. 1333
Characteristics, The Recovery-Voltage Analyzer for Determination of Circuit Recovery. Dunlap..........................958–62; disc. 1391
Chicago 12-Kv System, Surges on. Wollaston, Plumley...................260–5; disc. 604
Circuit Breaker for High-Voltage Service, A Conserved-Pressure Air-Blast. Rankin, Bennett..........................193–7; disc. 673
Circuit-Breaker Ratings, Power-. Van Sickle..........................882–4; disc. 1353
Circuit Breaker With 250,000-Kva Interrupting Capacity, A New Air. Dickinson, Nau..........................197–201; disc. 671
Circuit Breakers, Dielectric Strength of Oil for High-Voltage Testing of Oil. Lingal, Skeats, Braley..............................903–06
Circuit Breakers for Metal-Clad Switchgear, Medium-Capacity Air-Blast. Bennett, Wyman...................383–8; disc. 627
Circuit Breakers, Mechanical Simplicity of Air-Blast. Haberl, Jensen.....869–74; disc. 1355
Circuit Breakers, The Vertical-Flow Interrupter and Its Application to "Oil-Poor." Baker..........................440–5; disc. 635
Circuit for Theater Lighting, A Thyratron. Wischmeyer..............................1067–72
Circuit in the Theory of Polyphase Commutator Motors, A Generalized Equivalent. Coulthard..............................423–31
Circuit Instruments for the Higher Range of Audio Frequencies, Power. Lunas, MacGahan..........................1230–5
Circuit Interrupter Using Water, A High-Power Oilless. Leeds..............85–8; disc. 625
Circuit Interrupters, Dielectric Strength of Water in Relation to Use in. Slepian, Denault, Strom..................380–95; disc. 631
Circuit Performance, Capacitors and. Butler..........................408–15; disc. 646
Circuit Recovery Characteristics, The Recovery-Voltage Analyzer for Determination of. Dunlap....................958–62; disc. 1391
(Circuits) A New Method for Introducing Relaxed Initial Conditions in Transient Problems. Johnson..............................178–81
Circuits by Air Circuit Breakers in Cascade Arrangement, Protection of Low-Voltage. Anderson, Black..............1151–60; disc. 1356
Circuits, Criteria for Neutral Stability of Wye-Grounded-Primary Broken-Delta-Secondary Transformer. Shott, Peterson..........................997–1002; disc. 1394
Circuits, Engineering Requirements for Program Transmission. Cowan, McCurdy, Lattimer..........................142–7
Circuits, Fault Voltage Drop and Impedance at Short-Circuit Currents in Low-Voltage. Schurig....................479–87; disc. 654
Circuits for Ignitron Rectifiers, Excitation. Myers, Cox......................943–8; disc. 1358
Circuits in Synchronous-Machine Armatures, Short. Galbraith...................1024–9
Circuits, Linear Transformations in Three-Phase. Pipes.....................351–6; disc. 619
Circuits, Symmetrical Nomenclature of Three-Phase. Brady.............955–7; disc. 1402
Circuits, Vario-Losser. Bennett, Doba....17–22
Circuits With Capacitance Filters, Diode Rectifying. Waidelich...........1161–7; disc. 1388
City Transit System, Modern Motors Serve. Clardy, Atwell.......................850–4
Classification and Co-ordination of Short-Time and Intermittent Ratings and Applications. Hellmund.....................792–8; disc. 1323
Coefficients, A Short Method for Evaluating Determinants and Solving Systems of Linear Equations With Real or Complex. Crout..1235–41
Coils and Windings, Methods of Determining Natural Frequencies in. Bewley, Hagenguth, Jackson.................1145–50; disc. 1361
Cold-Cathode Tubes, Current Rating and Life of. Rockwood................901–03; disc. 1390
Columbia Gas and Electric Corporation, Increased Capacity and Interconnections of the. DeForest..............................451–8
Combinations, Relative Accuracy of Three-Phase Metering. Weller..........925–9; disc. 1336
Commercial Power Frequencies, An Improved Frequency Meter for. Knudsen..866–9; disc. 1334
(Committee Report) Bibliography of Relay Literature—1927–1939....................1435–47
(Committee Report) Power Supply for Resistance-Welding Machines—III.............185–92
(Committee Report) Protection of Power Transformers Against Lightning Surges..........................568–77; disc. 749
(Committee Report) Report on Apparatus Bushings.........................266; disc. 695
(Committee Report) Standard Basic Impulse Insulation Levels..........................1448
(Committee Report) Telemetering, Supervisory Control and Associated Circuits......1411–34
Committees for 1941–42, Officers and......1464–8
(Communication) A Push-Button-Tuned 50-Kw Broadcast Transmitter Rockwell, Lepple...1–3
(Communication) Aircraft Precipitation-Static Radio Interference. Starr............363–70
(Communication) An Electron Microscope for Practical Laboratory Service Zworykin, Hillier, Vance..........................157–62
(Communication) Basic Principles of the Varioplex Telegraph. Holcomb...............1102–08
(Communication) Engineering Requirements for Program Transmission Circuits. Cowan, McCurdy, Lattimer...................142–7
Communication Facilities of the U. S. Forest Service. Simson.......................971–6
(Communication) High-Voltage D-C Point Discharges. Starr.......................356–62
(Communication) Hollow Pipes of Relatively Small Dimensions. Barrow, Schaevitz......119–22
(Communication) Inductive Co-ordination of REA Distribution Systems and Telephone Systems. Plucknett, Smith, Taylor....586–95; disc. 723
(Communication) Picture Transmission by Submarine Cable. Milnor......105–08; disc. 756
(Communication) Radiobroadcasting in Canada. Frigon....................896–8; disc. 1357
(Communication) Rural Automatic Telephone Networks. Pfolliott.........1079–83; disc. 1304
(Communication) Television Transmission Over Wire Lines. Strieby, Wents..1090–6; disc. 1311
(Communication) The Measurement of Body Currents. Schwab.......................919–23
(Communication) The Varioplex—A New Development in Telegraphy. Shute...........181–4
(Communication) Vario-Losser Circuits. Bennett, Doba..............................17–22
(Communication) Wide-Band Square-Wave Generator, A. Bartelink.....................371–6
Commutation Observation, The "Black Band" Method of. Schroeder, Aydelott..........................446–51; disc. 659
Commutator Motors, A Generalized Equivalent Circuit in the Theory of Polyphase. Coulthard..............................423–31
Comparison of the Relative Efficiency of the Schafer and Pole-Top Methods of Artificial Respiration, A. Kouwenhoven, Hooker, Langworthy......................41–4; disc. 660
Complete Analysis of Motor Temperature Rise. Felix, Jungk...............578–86; disc. 684
Complex Coefficients, A Short Method for Evaluating Determinants and Solving Systems of Linear Equations With Real or. Crout..............................1235–41
Compressed-Air Breaker, A Vertical-Flow Outdoor. Ludwig, Baker.............217–22; disc. 672
Compressed Nitrogen, High-Voltage D-C Flashover of Solid Insulators in. Trump, Andrias..........................986–90; disc. 1393
Concepts, Single-Phase Motor Theory—a Correlation of the Cross-Field and Revolving-Field. Button....................507–12; disc. 664
Conditions in Three-Phase Systems Produced by Single-Phase Switching, Abnormal Voltage. Clarke, Peterson, Light.....329–30; disc. 618
Conductor Burndown From That Cause, Power Arc-Over on Overhead Distribution Lines and Newly Developed Equipment for Protection Against. Matthews.......596–604; disc. 684
Conductor Vibration, Measurement and Control of. Tebo...................1188–93; disc. 1380
Conductor Vibration—Theory of Torsional Dampers. Speight.............907–11; disc. 1376

Conductors, Formulas for the Inductance of Rectangular Tubular. Higgins..1046–50; disc. 1408
Conserved-Pressure Air-Blast Circuit Breaker for High-Voltage Service, A. Rankin, Bennett.......193–7; disc. 673
Construction Features, Powerton-Crawford 220-Kv Line—Design and. Oldacre, Wollaston.......1108–20; disc. 1297
Construction Theorem for Evaluating Operational Expressions Having a Finite Number of Different Roots, A. Cromwell...273–6; disc. 676
Control, A New Mercury Rheostatic Element for Regulation and. Oplinger...846–9; disc. 1386
Control by Capacitors, System Lower-Harmonic Voltages—Methods of Calculation and. Feaster, Harder..........1060–6; disc. 1310
Control in a Large Interconnection, Methods of System. Wild..............232–6; disc. 737
Control of Conductor Vibration, Measurement and. Tebo..................1188–93; disc. 1380
Control of the Switching Surge Voltages Produced by the Current-Limiting Power Fuse. Williams, Schuck..............214–17; disc. 678
Control, The Application of Ignitrons to Resistance-Welding. Bivens.......471–8; disc. 655
Control Transformers Operating in Parallel and Networks, Operation of Load Ratio. Starr.......1274–80; disc. 1407
Cooled Steel-Tank Rectifier Corrosion Problem, The Water-. Remscheid.....173–8; disc. 753
Co-ordinating Distribution Systems, An Automatically Reclosing Breaker for. Rawlins, Wallace.........................1021–4
Co-ordination of REA Distribution Systems and Telephone Systems, Inductive. Plucknett, Smith, Taylor...............586–95; disc. 723
Co-ordination of Short-Time and Intermittent Ratings and Applications. Classification and. Hellmund..................792–8; disc. 1323
Corrosion Problem, The Water-Cooled Steel-Tank Rectifier. Remscheid.........173–8; disc. 753
Crawford 220-Kv Line—Design and Construction Features, Powerton-. Oldacre, Wollaston.......1108–20; disc. 1297
Crawford 220-Kv Line-System Operating Features and Terminal Design, Powerton-. Wulfing, LeClair...................1084–9; disc. 1304
Criteria for Neutral Stability of Wye-Grounded-Primary Broken-Delta-Secondary Transformer Circuits. Shott, Peterson..997–1002; disc. 1394
Cross-Field and Revolving-Field Concepts, Single-Phase Motor Theory—a Correlation of the. Button......................507–12; disc. 664
Cross-Field Theory of the Capacitor Motor, The. Puchstein, Lloyd............58–62; disc. 667
Crystal Orientation on the Wear of Watt-Hour-Meter Bearings, Effects of Sapphire-. Goss.......811–14; disc. 1336
Current-Limiting Fuse, A New. Rawlins, Strom, Graybill.....................77–80; disc. 657
Current-Limiting Power Fuse, Control of the Switching Surge Voltages Produced by the. Williams, Schuck............214–17; disc. 678
Current Rating and Life of Cold-Cathode Tubes. Rockwood..................901–03; disc. 1390
Current Relay Channel to Other Uses, Possibilities and Methods of Extending a Carrier. Smith, Goldsborough................23–7; disc. 645
Current-Restrained Relays for Transformer Differential Protection, Harmonic-. Hayward......................377–82; disc. 622
Current-Transformer Characteristics, Bus Protection Independent of. Steeb..859–62; disc. 1365
Current Transformer for Bus Differential Protection, New. Kennedy, Sinks..1180–7; disc. 1363
Current Transformers, A Simple Method for Determination of Ratio Error and Phase Angle in. Wentz....................949–54; disc. 1369
Currents, An Experimental Investigation of Subharmonic. McCrumm......533–40; disc. 722
Currents in Dielectrics With a Cathode-Ray Tube Measurements of Pre-Breakdown. Race.......854–8; disc. 1388
Currents in Low-Voltage Circuits, Fault Voltage Drop and Impedance at Short-Circuit. Schurig.....................479–87; disc. 654
Currents in Squirrel-Cage Induction Motors, Rotor-Bar. Gault.........784–91; disc. 1327
Currents, System Short-Circuit. Hanna, Travers, Wagner, Woodrow, Skeats..877–81; disc. 1351
Currents, The Measurement of Body. Schwab.......919–23
Currents With Parallel Transformers Affect Differential Relaying, Prolonged Inrush. Hayward..................1096–1101; disc. 1305
Cycles, Behavior of Point Gaps at 60. Lebacqz.......44–8; disc. 651

D

Dampers, Conductor Vibration—Theory of Torsional. Speight...........907–11; disc. 1376
Damping and Synchronizing Torque of the Double-Fed Asynchronous Machine. Liwschitz...923–4
Damping in Synchronous Machines, Positive and Negative. Liwschitz................210–13
Damping of Electrical Machinery, Negative. Concordia, Carter..........116–19; disc. 752
Delta-Secondary Transformer Circuits, Criteria for Neutral Stability of Wye-Grounded-Primary Broken-. Shott, Peterson...997–1002; disc. 1394
(Derivatives) A New Method for Introducing Relaxed Initial Conditions in Transient Problems. Johnson..........................178–81
Design, A New Principle of Cable. Del Mar.......206–10; disc. 705
Design and Construction Features, Powerton-Crawford 220-Kv Line—. Oldacre, Wollaston..................1108–20; disc. 1297
Design Factors Involved in the Design of Domestic Motored Appliances. Packer...500–07; disc. 665
Design, Tennessee Valley Authority Hydroelectric Stations—Electrical. Hopkins.......1281–93; disc. 1408
Designing Capacitor Motors, The Equal-Volt-Ampere Method of. Trickey...990–2; disc. 1399
Designs Require Special Features to Insure Radio Quietness, Some Insulator. Miller.......62–6; disc. 657
Detection of Initial Failure in High-Voltage Insulation, The. Whitehead, Shaw..267–72; disc. 761
Determinants and Solving Systems of Linear Equations With Real or Complex Coefficients, A Short Method for Evaluating. Crout...1235–41
Determination of Magnitude and Phase Angle of Electrical Quantities, The. Walker.......837–9; disc. 1333
Determination of Ratio Error and Phase Angle, in Current Transformers, A Simple Method for. Wentz..................949–54; disc. 1369
Determining Natural Frequencies in Coils and Windings, Methods of. Bewley, Hagenguth, Jackson..................1145–50; disc. 1361
Development in Lightning Protection of Stations. Whitehead...............898–900; disc. 1372
Development of the Glow-Switch. Hays.......223–6; disc. 723
Diathermy Apparatus and Frequency-Control Possibilities, Short-Wave. Gieringer...459–64
Dielectric, High-Pressure Gas As a. Nonken.......1017–20; disc. 1405
Dielectric-Loss and Power-Factor Method for Field Investigation of Electrical Insulation, The A-C. Doble..........934–9; disc. 1348
Dielectric Strength of Glass—an Engineering Viewpoint, The. Shand........814–18; disc. 1331
Dielectric Strength of Oil for High-Voltage Testing of Oil Circuit Breakers. Lingal, Skeats, Braley............................903–06
Dielectric Strength of Water in Relation to Use in Circuit Interrupters. Slepian, Denault, Strom......................389–95; disc. 631
Dielectrics With a Cathode-Ray Tube, Measurements of Pre-Breakdown Currents in. Race.......854–8; disc. 1388
Diesel Engine, Investigation of Starting Requirements of a 660-Horsepower Locomotive. Davidson, Lamborn..........31–4; disc. 632
Differential Protection, Harmonic-Current-Restrained Relays for Transformer. Hayward.......377–82; disc. 622
Differential Protection, New Current Transformer for Bus. Kennedy, Sinks...1180–7; disc. 1363
Differential Relaying, Prolonged Inrush Currents With Parallel Transformers Affect. Hayward.................1096–1101; disc. 1305
Diffusion in Fluid-Flow Arc Extinction, Displacement and. Slepian..........162–7; disc. 643
Dimensions, Hollow Pipes of Relatively Small. Barrow, Schaevitz.........................119–22
Diode Rectifying Circuits With Capacitance Filters. Waidelich.................1161–7; disc. 1388
D-C Breakdown Strength of Air and of Freon in a Uniform Field at High Pressures. Trump, Safford, Cloud.................132–5; disc. 676
D-C Flashover of Solid Insulators in Compressed Nitrogen, High-Voltage. Trump, Andrias.......986–90; disc. 1393
D-C Machine Flashover and Bus Short-Circuit Protection. Montgomery, Sellers.......1168–73; disc. 1370
D-C Point Discharges, High-Voltage. Starr..356–62
D-C Wattmeter of the Shunted Type, An Improved Type of. MacGahan..........4–7; disc. 633
Directional Relay, An Improved Polyphase. Hoard.......................246–8; disc. 681
Discharges, High-Voltage D-C Point. Starr..356–62
Displacement and Diffusion in Fluid-Flow Arc Extinction. Slepian...........162–7; disc. 643

Impulse Strength as a Measure of Cable Quality. Komives........929–34; disc. 1339
Incandescent Lamp Situation From the Engineering Point of View, The. Millar........1174–80; disc. 1387
Increased Capacity and Interconnections of the Columbia Gas and Electric Corporation. DeForest........451–8
Indicator for Measuring Static and Dynamic Pressures, An Electrical Engine. Martin, Grinstead, Frawley........513–23; disc. 725
Inductance of Rectangular Tubular Conductors, Formulas for the. Higgins...1046–50; disc. 1408
Induction-Motor Performance Calculation, Single-Phase. Himebrook........55–8; disc. 666
Induction Motors During Single-Phase Operation, Overvoltages in Polyphase. Macmillan, Carter........819–23; disc. 1328
Induction Motors, Rotor-Bar Currents in Squirrel-Cage. Gault........784–91; disc. 1327
Induction Motors, The Use of Auxiliary Impedances in the Single-Phase Operation of Polyphase. Ager........494–9; disc. 660
Induction Motors, Transient Overspeeding of. Ager........1030–2
Induction Motors With Series Capacitors, Self-Excitation of. Wagner....1241–7; disc. 1391
Induction Motors, With Special Reference to Plugging, Transient Torques in Squirrel-Cage. Gilfillan, Kaplan........1200–09; disc. 1363
Inductive Co-ordination of REA Distribution Systems and Telephone Systems. Plucknett, Smith, Taylor........586–95; disc. 723
Industrial Plants, Secondary Networks to Serve. Powel, Barnett........154–6; disc. 698
Industrial Plants, Enclosed Bus-Bar Electrical Distribution Systems for. Carlson........297–302; disc. 700
Industrial Tool, Radiant Heat—A Full-Fledged. Goodell........464–71
Inherent Overheating Protection of Single-Phase Motors, The. Potter........993–6; disc. 1400
Initial Breakdown Voltages in Air, Calculation of. Ver Planck........99–104
Initial Failure in High-Voltage Insulation, The Detection of. Whitehead, Shaw..267–72; disc. 761
Inrush Currents With Parallel Transformers Affect Differential Relaying, Prolonged. Hayward........1096–1101; disc. 1305
Installation, Alcoa Rectifier. Housley, Winograd........1266–74; disc. 1409
(Instruments) A Cathode-Ray Method of Wave Analysis. Johnson........1032–6; disc. 1398
(Instruments) A Turbine-Governor Performance Analyzer. Osbon........963–7; disc. 1401
(Instruments) Ampere-Squared-Second Recorder. Rich........839–42
(Instruments) An Automatic Printing Ammeter. LeClair........93–9; disc. 757
(Instruments) An Improved Frequency Meter for Commercial Power Frequencies. Knudsen........866–9; disc. 1334
(Instruments) An Improved Type of D-C Wattmeter of the Shunted Type. MacGahan........4–7; disc. 633
(Instruments) Braking Magnets for Watt-Hour Meters. Kinnard, Goss......431–9; disc. 653
(Instruments) Bushing Tests. Brownlee, Wickham........940–2; disc. 1344
(Instruments) Cathode-Ray Oscillograph With Rotating-Drum Camera, A. Downie...984–6
(Instruments) Criteria for Neutral Stability of Wye-Grounded-Primary Broken-Delta-Secondary Transformer Circuits. Shott, Peterson........997–1002; disc. 1394
(Instruments) Effect of Sapphire-Crystal Orientation on the Wear of Watt-Hour Meter Bearings. Goss........811–14; disc. 1336
Instruments for the Higher Range of Audio Frequencies, Power Circuit. Lunas. MacGahan........1230–5
(Instruments) Magnetic Fields in Watt-Hour Meters. Keener, Faucett, Helm..202–05; disc. 758
(Instruments) Relative Accuracy of Three-Phase Metering Combinations. Weller........925–9; disc. 1336
(Instruments) Testing of Elevator Buffers by Electrical Means. Kimberly........53–4
(Instruments) The Modern A-C Network Calculator. Parker........977–82; disc. 1395
(Instruments) The Shielding of Permanent Magnets From Transient Magnetic Fields. Wey........875–7; disc. 1338
(Instruments) Volt-Time Areas of Impulse Spark-Over. Hagenguth........803–10; disc. 1312
Insulation and Operating Experience, Field Power-Factor Testing of Transformer. Whitmer........605–11; disc. 741
Insulation by Lightning Arresters, The Protection of Solid. MacCarthy, Carpenter........912–15; disc. 1349
Insulation, Factors Influencing the Mechanical Strength of Cellulose. Clark..778–83; disc. 1321
Insulation, Field Testing of Generator. (Committee Report)........1003–11; disc. 1314
Insulation Levels, Standard Basic Impulse. (Committee Report)........1448
Insulation Level for Lightning Protection of Medium-Voltage Lines, Minimum. Ekvall........128–32; disc. 719
Insulation, Power-Factor Testing of Transformer. Hodtum........28–30; disc. 647
Insulation Testing by the Power-Factor Method, Bushing and Associated. Baltzly, Schlottere........308–12; disc. 744
Insulation, The A-C Dielectric-Loss and Power-Factor Method for Field Investigation of Electrical. Doble........934–9; disc. 1348
Insulation, The Basis for the Non-destructive Testing of. Field........890–5; disc. 1347
Insulation, The Detection of Initial Failure in High-Voltage. Whitehead, Shaw........267–72; disc. 761
Insulator Designs Require Special Features to Insure Radio Quietness, Some. Miller........62–6; disc. 657
Insulators in Compressed Nitrogen, High-Voltage D-C Flashover of Solid. Trump, Andrias........986–90; disc. 1393
Insure Radio Quietness, Some Insulator Designs Require Special Features to. Miller........62–6; disc. 657
Interconnected Systems, Prime-Mover Speed Governors for. Caughey, McClure........147–51; disc. 728
Interconnection, Methods of System Control in a Large. Wild........232–6; disc. 737
Interconnections of the Columbia Gas and Electric Corporation, Increased Capacity and. DeForest........451–8
Interference, Aircraft Precipitation-Static Radio. Starr........363–70
Intermittent Ratings and Applications, Classification and Co-ordination of Short-Time and. Hellmund........792–8; disc. 1323
Interrupter and Its Application to "Oil-Poor" Circuit Breakers, The Vertical-Flow. Baker........440–5; disc. 635
Interrupter Using Water, A High-Power Oilless Circuit. Leeds........85–8; disc. 625
Interrupters, Dielectric Strength of Water in Relation to Use in Circuit. Slepian, Denault, Strom........389–95; disc. 631
Interrupting Capacity, A New Air Circuit Breaker With 250,000-Kva. Dickinson, Nau........197–201; disc. 671
Interruption, The Geometry of Arc. Boehne........524–32; disc. 675
Investigation of Electrical Insulation, The A-C Dielectric-Loss and Power-Factor Method for Field. Doble........934–9; disc. 1348
Investigation of Starting Requirements of a 660-Horsepower Locomotive Diesel Engine. Davidson, Lamborn........31–4; disc. 632
Investigation of Subharmonic Currents, An Experimental. McCrumm........533–40; disc. 722
Investigations of Lightning, Field. Wagner, McCann, Beck........1222–30; disc. 1381

L

Laboratory—III, Lightning Strokes in Field and. Bellaschi..........1248–56; disc. 1392.
Laboratory Service, An Electron Microscope for Practical. Zworykin, Hillier, Vance..157–62
Lamp Situation From the Engineering Point of View, The Incandescent. Millar..........1174–80; disc. 1387
Lamps, Some Characteristics and Applications of Negative-Glow. Ferree.......8–12; disc. 622
Large Electric-Arc Furnaces—Performance and Power Supply. Jones, Stearns..763–9; disc. 1325
Lead Storage Batteries in the Transportation Field. Whitehurst..........303–07; disc. 683
Level for Lightning Protection of Medium-Voltage Lines, Minimum Insulation. Ekvall..........128–32; disc. 719
Levels of Transformers A Study of Sound. Fahnoe..........277–83; disc. 748
(Light, Production and Application of) Development of the Glow-Switch. Hays..........223–6; disc. 723
(Light, Production and Application of) Radiant Heat—a Full-Fledged Industrial Tool. Goodell..........464–71
(Light, Production and Application of) Some Characteristics and Applications of Negative-Glow Lamps. Ferree..........8–12; disc. 622
(Light, Production and Application of) The Incandescent Lamp Situation From the Engineering Point of View. Millar....1174–80; disc. 1387
Lighting, A Thyratron Circuit for Theater. Wischmeyer..........1067–72
Lightning-Arrester Performance Characteristics, Line-Type. (Committee Report)......982–3
Lightning Arresters, The Protection of Solid Insulation by. MacCarthy, Carpenter..........912–15; disc. 1349
Lightning, Field Investigations of. Wagner, McCann, Beck..........1222–30; disc. 1381
Lightning Protection of Medium-Voltage Lines, Minimum Insulation Level for. Ekvall..........128–32; disc. 719
Lightning Protection of Stations, Development in. Whitehead..........898–900; disc. 1372
Lightning Protection on Transmission Lines, Experience With Preventive. Waldorf..........249–54; disc. 701
Lightning Strokes in Field and Laboratory—III. Bellaschi..........1248–56; disc. 1392
Lightning Surges, Protection of Power Transformers Against. (Committee Report)..........568–77; disc. 749
Lightning to the Empire State Building. McEachron..........885–90; disc. 1377
Limitations of Long-Distance A-C Power-Transmission Systems, Stability. Clarke, Crary..........1051–9; disc. 1299
Limiting Fuse, A New Current-. Rawlins, Strom, Graybill..........77–80; disc. 657
Line—Design and Construction Features, Powerton-Crawford 220-Kv. Oldacre, Wollaston..........1108–20; disc. 1297
Line-System Operating Features and Terminal Design, Powerton-Crawford 220-Kv. Wulfing, LeClair..........1084–9; disc. 1304
Line-Type Lightning-Arrester Performance Characteristics. (Committee Report)........982–3
Linear Equations With Real or Complex Coefficients, A Short Method for Evaluating Determinants and Solving Systems of. Crout..........1235–41
Linear Transformations in Three-Phase Circuits. Pipes..........351–6; disc. 619
Lines and Distribution Feeders, Sensitive Ground Protection for Transmission. Gross..968–71
Lines and Newly Developed Equipment for Protection Against Conductor Burndown From That Cause, Power Arc-Over on Overhead Distribution. Matthews..........596–604; disc. 684
Lines, Experience With Preventive Lightning Protection on Transmission. Waldorf..........249–54; disc. 701
Lines, Five Years' Experience With Ultrahigh-Speed Reclosing of High-Voltage Transmission. Sporn, Muller..........241–6; disc. 690
Lines, Minimum Insulation Level for Lightning Protection of Medium-Voltage. Ekvall..........128–32; disc. 719
Lines, Shielding of Transmission. Wagner, McCann, MacLane..........313–28; disc. 612
Lines, Television Transmission Over Wire. Strieby, Wentz..........1090–6; disc. 1311
Lines, Transient Analysis of Completely Transposed Multiconductor Transmission. Pipes..........346–51; disc. 621
Link, The Protective. Hodnette, Leonard..........226–9; disc. 679
Liquids, Photographic Study of A-C Arcs in Flowing. Slepian, Browne.......823–8; disc. 1330
Load, A Power-System Governor Sensitive to Frequency and. Curtis..........89–92; disc. 731
Load Radio Control Transformers Operating in Parallel and in Networks, Operating. Starr..........1274–80; disc. 1407
Load Stations, A New Transformer for Base-. Sporn, Putman..........916–18; disc. 1358
Load Swings, System Bauman, Mans, McCormack, Seeley..........541–7; disc. 735
Locomotive Application, Electric. Brandenstein, MacLeod..........1210–15; disc. 1382
Locomotive Diesel Engine, Investigation of Starting Requirements of a 660-Horsepower. Davidson, Lamborn ....31–4, disc. 632
Long-Distance A-C Power-Transmission Systems, Stability Limitations of. Clarke, Crary..........1051–9; disc. 1299
Loss and Power-Factor Method for Field Investigation of Electrical Insulation, The A-C Dielectric. Doble..........934–9; disc. 1348
Losser Circuits, Vario-. Bennett, Doba......17–22
Low-Voltage A-C Systems, Short-Circuit Calculating Procedure for. Darling..1121–36; disc. 1294
Low-Voltage Circuits by Air Circuit Breakers in Cascade Arrangement, Protection of. Anderson, Black..........1150–60; disc. 1356
Lower-Harmonic Voltages—Methods of Calculation and Control by Capacitors, System. Feaster, Harder..........1060–6; disc. 1310

M

Machine Armature, Short Circuits in Synchronous-. Galbraith..........1024–9
Machine, Damping and Synchronizing Torque of the Double-Fed Asynchronous. Liwschitz..........923–4
Machine Flashover and Bus Short-Circuit Protection, D-C. Montgomery, Sellers..........1168–73; disc. 1370
Machinery, Negative Damping of Electrical. Concordia, Carter..........116–19; disc. 752
Machines, Power Supply for Resistance-Welding. Part III..........185–92
Magnetic Fields in Watt-Hour Meters. Keener, Faucett, Helm..........202–05; disc. 758
Magnetic Vibration and Noise of Two-Pole Turbine Generators, Suppression of. Penniman, Taylor..........283–8; disc. 745
Magnets for Watt-Hour Meters, Braking. Kinnard, Goss..........431–9; disc. 653
Magnets From Transient Magnetic Fields, The Shielding of Permanent. Wey..875–7; disc. 1338
Magnitude and Phase Angle of Electrical Quantities, The Determination of. Walker..........837–9; disc. 1333
Measuring Static and Dynamic Pressures, An Electrical Engine Indicator for. Martin, Grinstead, Frawley..........513–23; disc. 725
Measurement and Control of Conductor Vibration. Tebo..........1188–93; disc. 1380
Measurement of Body Currents, The. Schwab..........919–23
(Measurements) A New High-Speed Thermal Wattmeter. Miller..........37–40; disc. 633
(Measurements) Behavior of Point Gaps at 60 Cycles. Lebacqz..........44–8; disc. 651
(Measurements) Bushing Tests. Brownlee, Wickham..........940–2; disc. 1344
(Measurements) Cathode-Ray Oscillograph With Rotating-Drum Camera, A. Downie..984–6
(Measurements) High-Potential Testing Equipment for Quantity Production. Summers..........289–92; disc. 756
Measurements of Pre-Breakdown Currents in Dielectrics With a Cathode-Ray Tube. Race..........854–8; disc. 1388
(Measurements) Testing of Elevator Buffers by Electrical Means. Kimberly..........53–4
(Measurements) The A-C Dielectric-Loss and Power-Factor Method for Field Investigation of Electrical Insulation. Doble..........934–9; disc. 1348
(Measurements) The Determination of Magnitude and Phase Angle of Electrical Quantities. Walker..........837–9; disc. 1333
(Measurements) Volt-Time Areas of Impulse Spark-Over. Hagenguth..........803–10; disc. 1312
Mechanical Simplicity of Air-Blast Circuit Breakers. Haberl, Jensen..........869–74; disc. 1355
Mechanical Strength of Cellulose Insulation, Factors Influencing the. Clark...778–83; disc. 1321
Medium-Capacity Air-Blast Circuit Breakers for Metal-Clad Switchgear. Bennett, Wyman..........383–8; disc. 627
Medium-Voltage Lines, Minimum Insulation Level for Lightning Protection of. Ekvall..........128–32; disc. 719
Mercury-Arc Rectifiers for Traction Service, Glass-Bulb. Woolgar..........843–6; disc. 1383
Mercury Rheostatic Element for Regulation and Control, A New. Oplinger..846–9; disc. 1386
Metal-Clad Switchgear, Medium-Capacity Air-Blast Circuit Breakers for. Bennett, Wyman..........383–8; disc. 637
Meter Bearings, Effect of Sapphire-Crystal Orientation on the Wear of Watt-Hour-. Goss..........811–14; disc. 1336
Meter for Commercial Power Frequencies, An Improved Frequency. Knudsen...866–9; disc. 1334
Metering Combinations, Relative Accuracy of Three-Phase. Weller.......925–9; disc. 1336
Meters, Braking Magnets for Watt-Hour. Kinnard, Goss..........431–9; disc. 653
Meters, Magnetic Fields in Watt-Hour. Keener, Faucett, Helm..........202–05; disc. 758
Method, Bushing and Associated Insulation Testing by the Power-Factor. Baltzly, Schlotterer..........308–12; disc. 744
Method for Determination of Ratio Error and Phase Angle in Current Transformers, A Simple. Wentz..........949–54; disc. 1369
Method for Evaluating Determinants and Solving Systems of Linear Equations With Real or Complex Coefficients, A Short. Crout..1235–41
Method for Introducing Relaxed Initial Conditions in Transient Problems, A New. Johnson..........178–81
Method of Calculating Single-Phase Motor Performance, The Apparent-Impedance. Morrill..........1037–41
Method of Designing Capacitor Motors, the Equal-Volt-Ampere. Trickey.....990–2; disc. 1399
Method of Wave Analysis, A Cathode-Ray. Johnson..........1032–6; disc. 1398
Methods of Determining Natural Frequencies in Coils and Windings. Bewley, Hagenguth, Jackson..........1145–50; disc. 1361
Methods of Extending a Carrier Current Relay Channel to Other Uses, Possibilities and. Smith, Goldsborough..........23–7; disc. 645
Methods of Solving Discrete Nonlinear Problems in Electrical Engineering, Analytical. Keller..........1194–1200; disc. 1389
Methods of System Control in a Large Interconnection. Wild..........232–6; disc. 737
Microscope for Practical Laboratory Service, An Electron. Zworykin, Hillier, Vance...157–62
Minimum Insulation Level for Lightning Protection of Medium-Voltage Lines. Ekvall..........128–32; disc. 719
Modern A-C Network Calculator, The. Parker..........977–82; disc. 1395
Modern Motors Serve City Transit Systems. Clardy, Atwell..........850–4
Modern Relaying for A-C Secondary Network Systems. Beeman..........237–41; disc. 683
Modern Service, High-Voltage Bushings Designed to Meet. Brandt, Rorden..255-00; disc. 696
Motor Performance Calculation, Single Phase Induction. Himebrook..........55–8; disc. 666
Motor Performance, The Apparent-Impedance Method of Calculating Single-Phase. Morrill..........1037–41
Motor Temperature Rise, Complete Analysis of. Felix, Jungk..........578–86; disc. 684
Motor, The Cross-Field Theory of the Capacitor. Puchstein, Lloyd..........58–62; disc. 667
Motor Theory—a Correlation of the Cross-Field and Revolving-Field Concepts, Single-Phase. Button..........507–12; disc. 664
Motor, Theory of the Brush-Shifting A-C. Conrad, Zweig, Clarke.
  Part I..........829–34
  Part II..........834–36
Motored Appliances, Design Factors Involved in the Design of Domestic. Packer 500–07; disc. 665
Motors, A Generalized Equivalent Circuit in the Theory of Polyphase Commutator. Coulthard..........423–31
Motors Automatically, Two New Methods of Accelerating Electric. Leitch..487–93; disc. 655
Motors During Single-Phase Operation, Overvoltages in Polyphase Induction. Macmillan, Carter..........819–23; disc. 1328
Motors, Performance Calculations on Capacitor. Trickey..........73–6; disc. 662
Motors, Performance Calculations on Repulsion. Trickey..........67–73; disc. 661
Motors, Rotor-Bar Currents in Squirrel-Cage Induction. Gault..........784–91; disc. 1327
Motors Serve City Transit Systems, Modern. Clardy, Atwell..........850–4
Motors, Some Acceleration Tests on Large Synchronous Pump. Ager......416–22; disc. 649
Motors, The Equal-Volt-Ampere Method of Designing Capacitor. Trickey..990–2; disc. 1399
Motors, The Inherent Overheating Protection of Single-Phase. Potter.......993–6; disc. 1400
Motors, The Use of Auxiliary Impedances in the Single-Phase Operation of Polyphase Induction. Ager..........494–9; disc. 660

Motors, Transient Overspeeding of Induction. Ager........1030–2

Motors With Series Capacitors, Self-Excitation of Induction. Wagner........1241–7; disc. 1391

Motors, With Special Reference to Plugging, Transient Torques in Squirrel-Cage Induction. Gilfillan, Kaplan........1200–09; disc. 1363

Multiconductor Transmission Lines, Transient Analysis of Completely Transposed. Pipes........346–51; disc. 621

N

Natural Frequencies in Coils and Windings, Methods of Determining. Bewley, Hagenguth, Jackson........1145–50; disc. 1361

Negative Damping in Synchronous Machines, Positive and. Liwschitz........210–13

Negative Damping of Electrical Machinery. Concordia, Carter........116–19; disc. 752

Negative-Glow Lamps, Some Characteristics and Applications of. Ferree........8–12; disc. 622

(NEMA) Standard Basic Impulse Insulation Levels. (Committee Report)........1448

Network Calculator, The Modern A-C. Parker........977–82; disc. 1395

Network Systems, Modern Relaying for A-C Secondary. Beeman........237–41; disc. 683

Networks, Operation of Load Radio Control Transformers Operating in Parallel and in. Starr........1274–80; disc. 1407

Networks, Rural Automatic Telephone. Ffolliott........1079–83; disc. 1304

Networks to Serve Industrial Plants, Secondary. Powel, Barnett........154–6; disc. 698

Neutral Stability of Wye-Grounded-Primary Broken-Delta-Secondary Transformer Circuits, Criteria for. Shott, Peterson...997–1002; disc. 1394

Neutralizer Systems, An Analysis of Transient and Sustained Voltages in Ground-Fault. Farnham, Hunter, Peterson........1257–66; disc. 1394

New Current Transformer for Bus Differential Protection. Kennedy, Sinks...1180–7; disc. 1363

Nitrogen, High-Voltage D-C Flashover of Solid Insulators in Compressed. Trump, Andrias........986–90; disc. 1393

Noise of Transformers, The Audio. Sealey........109–12; disc. 745

Noise of Two-Pole Turbine Generators, Suppression of Magnetic Vibration and. Penniman, Taylor........283–8; disc. 745

Nomenclature of Three-Phase Circuits, Symmetrical. Brady........955–7; disc. 1402

Nondestructive Testing of Insulation, The Basis for the. Field........890–5; disc. 1347

Nonlinear Problems in Electrical Engineering, Analytical Methods of Solving Discrete. Keller........1194–1200; disc. 1389

Novel Reclosing Relay, A. Bobo..1041–5; disc. 1403

O

Observation, the "Black Band" Method of Commutation. Schroeder, Aydelott........446–51; disc. 659

Officers and Committees for 1941–42........1464–8

Oil for High-Voltage Testing of Oil Circuit Breakers, Dielectric Strength of. Lingal, Skeats, Braley........903–06

Oilless Circuit Interrupter Using Water, A High-Power. Leeds........85–8; disc. 625

Oil- or Gas-Blast Power Fuse, A Double-Break. Hill........402–07; disc. 646

"Oil-Poor" Circuit Breakers, The Vertical-Flow Interrupter and Its Application to. Baker........440–5; disc. 635

Operating Experience, Field Power-Factor Testing of Transformer Insulation and. Whitmer........605–11; disc. 741

Operating Features and Terminal Design, Powerton-Crawford 220-Kv Line-System. Wulfing, LeClair........1084–9; disc. 1304

Operation of Load Ratio Control Transformers Operating in Parallel and in Networks. Starr........1274–80; disc. 1407

Operational Expressions Having a Finite Number of Different Roots, A Construction Theorem for Evaluating. Cromwell........273–6; disc. 676

Orientation on the Wear of Watt-Hour-Meter Bearings, Effect of Sapphire-Crystal. Goss........811–14; disc. 1336

Oscillograms, Analysis of Short-Circuit. Kuyper........151–3; disc. 752

Oscillograph With Rotating-Drum Camera, A Cathode-Ray. Downie........984–6

Outdoor Compressed-Air Breaker, A Vertical-Flow. Ludwig, Baker........217–22; disc. 672

Overexciting Transformers on System Voltage Wave Shapes and Power Factor, The Effect of. Butler, Pope........49–53; disc. 656

Overhead Distribution Lines and Newly Developed Equipment for Protection Against Conductor Burndown From That Cause, Power Arc-Over on. Matthews........596–604; disc. 684

Overheating Protection of Single-Phase Motors, The Inherent. Potter........993–6; disc. 1400

Overspeeding of Induction Motors, Transient. Ager........1030–2

Overvoltages in Polyphase Induction Motors During Single-Phase Operation. Macmillan, Carter........819–23; disc. 1328

P

Parallel Transformers Affect Differential Relaying, Prolonged Inrush Currents With. Hayward........10[illegible]–1101; disc. 1305

Performance Analyzer, A Turbine-Governor. Osbon........963–7; disc. 1401

Performance Calculation, Single-Phase Induction-Motor. Himebrook........55–8; disc. 666

Performance, The Apparent-Impedance Method of Calculating Single-Phase Motor. Morrill........1037–41

Permanent Magnets From Transient Magnetic Fields, The Shielding of. Wey..875–7; disc. 1338

Phase Angle in Current Transformers, A Simple Method for Determination of Ratio Error and. Wentz........949–54; disc. 1369

Phase Angle of Electrical Quantities, The Determination of Magnitude and. Walker........837–9; disc. 1333

Photographic Study of A-C Arcs in Flowing Liquids. Slepian, Browne........823–8; disc. 1330

Picture Transmission by Submarine Cable. Milnor........105–08; disc. 756

Pilot-Wire Relay, An Improved A-C. Neher, McConnell........12–17; disc. 638

Pipes of Relatively Small Dimensions, Hollow. Barrow, Schaevitz........119–22

Plant Expansion, A Distribution System for War-Time. McKeever........862–5; disc. 1385

Plants, Enclosed Bus-Bar Electrical Distribution Systems for Industrial. Carlson........297–302; disc. 700

Plants, Secondary Networks to Serve Industrial. Powel, Barnett........154–6; disc. 698

Plugging, Transient Torques in Squirrel-Cage Induction Motors, With Special Reference to. Gilfillan, Kaplan........1200–09; disc. 1363

Point Discharges, High-Voltage D-C. Starr........356–62

Point Gaps at 60 Cycles, Behavior of. Lebacqz........44–8; disc. 651

Pole-Top Methods of Artificial Respiration, A Comparison of the Relative Efficiency of the Schafer and. Kouwenhoven, Hooker, Langworthy........41–4; disc. 660

Polyphase Commutator Motors, A Generalized Equivalent Circuit in the Theory of. Coulthard........423–31

Polyphase Directional Relay, An Improved. Hoard........246–8; disc. 681

Polyphase Induction Motors During Single-Phase Operation. Overvoltages in. Macmillan, Carter........819–23; disc. 1328

Polyphase Induction Motors, The Use of Auxiliary Impedances in the Single-Phase Operation of. Ager........494–9; disc. 660

Positive and Negative Damping in Synchronous Machines. Liwschitz........210–13

Possibilities and Methods of Extending a Carrier Current Relay Channel to Other Uses. Smith, Goldsborough........23–7; disc. 645

Potential Testing Equipment for Quantity Production, High. Summers........289–92; disc. 756

(Power Applications, Industrial) Overvoltages in Polyphase Induction Motors During Single-Phase Operation. Macmillan, Carter........819–23; disc. 1328

(Power Applications, Industrial) A Distribution System for War-Time Plant Expansion. McKeever........862–5; disc. 1385

(Power Applications, Industrial) A New Mercury Rheostatic Element for Regulation and Control. Oplinger........846–9; disc. 1386

(Power Applications, Industrial) Enclosed Bus-Bar Electrical Distribution Systems for Industrial Plants. Carlson........297–302; disc. 700

Power Applications, Industrial) Fault Voltage Drop and Impedance at Short-Circuit Currents in Low-Voltage Circuits. Schurig........479–87; disc. 654

(Power Applications, Industrial) Secondary Networks to Serve Industrial Plants. Powel, Barnett........154–6; disc. 698

(Power Applications, Industrial) Short-Circuit Calculating Procedure for Low-Voltage A-C Systems. Darling........1121–36; disc. 1294

(Power Applications, Industrial) Two New Methods of Accelerating Electric Motors Automatically. Leitch........487–93; disc. 655

Power Arc-Over on Overhead Distribution Lines and Newly Developed Equipment for Protection Against Conductor Burndown From That Cause. Matthews........596–604; disc. 684

Power-Circuit-Breaker Ratings. Van Sickle........882–4; disc. 1353

Power Circuit Instruments for the Higher Range of Audio Frequencies. Lunas, MacGahan........1230–5

Power-Factor Method, Bushing and Associated Insulation Testing by the. Baltzly, Schlottere........308–12; disc. 744

Power-Factor Method for Field Investigation of Electrical Insulation, The A-C Dielectric-Loss and. Doble........934–9; disc. 1348

Power-Factor Testing of Transformer Insulation. Hodtum........28–30; disc. 647

Power-Factor Testing of Transformer Insulation and Operating Experience, Field. Whitmer........605–11; disc. 741

Power Factor, The Effect of Overexciting Transformers on System Voltage Wave Shapes and. Butler, Pope........49–53; disc. 656

Power Frequencies, An Improved Frequency Meter for Commercial. Knudsen..866–9; disc. 1334

Power Fuse, A Double-Break Oil or Gas-Blast. Hill........402–07; disc. 646

Power Fuse, Control of the Switching Surge Voltages Produced by the Current-Limiting. Williams, Schuck........214–17; disc. 678

(Power Generation) A Power-System Governor Sensitive to Frequency and Load. Curtis........89–92; disc. 731

(Power Generation) A Turbine-Governor Performance Analyzer. Osbon........963–7; disc. 1401

(Power Generation) An Electrical Governor. Morgan........80–4

(Power Generation) Increased Capacity and Interconnections of the Columbia Gas and Electric Corporation. DeForest........451–8

(Power Generation) Methods of System Control in a Large Interconnection. Wild...232–6; disc. 737

(Power Generation) Prime-Mover Speed Governors for Interconnected Systems. Caughey, McClure........147–51; disc. 728

(Power Generation) System Load Swings. Bauman, Manz, McCormack, Seeley...541–7; disc. 735

(Power Generation) System Stability. Gay........168–73; disc. 739

(Power Generation) Tennessee Valley Authority Hydroelectric Stations—Electrical Design. Hopkins........1281–93; disc. 1408

Power Supply for Resistance-Welding Machines—III........185–92

Power Supply, Large Electric-Arc Furnaces—Performance and. Jones, Stearns...763–9; disc. 1325

Power-System Frequency Variations and Tie-Line Power Swings, Effect of Prime-Mover Speed Governor Characteristics on. Concordia, Crary, Parker........559–67; disc. 733

Power System Governing—the Problem. Dougherty, Hayward, Monteith, Griscom........547–58; disc. 731

Power Systems, Arcing Faults in. Concordia, Peterson........340–6; disc. 614

Power Systems, Superposition Methods for Calculating Effects of Additions to. Rettig........396–401; disc. 648

Power Transformers Against Lightning Surges, Protection of. (Committee Report)........568–77; disc. 749

Power-Transmission Systems, Stability Limitations of Long-Distance A-C. Clarke, Crary........1051–9; disc. 1299

Powerton-Crawford 220-Kv Line—Design and Construction Features. Oldacre, Wollaston........1108–20; disc. 1297

Powerton-Crawford 220-Kv Line-System Operating Features and Terminal Design. Wulfing, LeClair........1084–9; disc. 1304

Practical Laboratory Service, An Electron Microscope for. Zworykin, Hillier, Vance...157–62

Precipitation-Static Radio Interference, Aircraft. Starr........363–70

Pressure, The Electric Strength of Air at High. Part II. Skilling, Brenner...112–15; disc. 677

Pressures, An Electrical Engine Indicator for Measuring Static and Dynamic. Martin, Grinstead, Frawley........513–23; disc. 725

Pressures, D-C Breakdown Strength of Air and of Freon in a Uniform Field at High. Trump, Safford, Cloud................132–5; disc. 676
Prime-Mover Speed Governor Characteristics on Power-System Frequency Variations and Tie-Line Power Swings, Effect of. Concordia, Crary, Parker..............559–67; disc. 733
Prime-Mover Speed Governors for Interconnected Systems. Caughey, McClure...147–51; disc. 728
Principle of Cable Design, A New. Del Mar............................206–10; disc. 705
Principles of the Variplex Telegraph, Basic. Holcomb..............................1102–08
Printing Ammeter, Automatic. LeClair..................................93–9; disc. 757
Problems in Electrical Engineering, Analytical Methods of Solving Discrete Nonlinear. Keller.................1194–1200; disc. 1389
Procedure for Low-Voltage A-C Systems, Short-Circuit Calculating. Darling..1121–36; disc. 1294
Process of Scale Removal From Steel, Electrolytic. Neblett......................294–6; disc. 761
Production, High-Potential Testing Equipment for Quantity. Summers........289–92; disc. 756
Program Transmission Circuits, Engineering Requirements for. Cowan, McCurdy, Lattimer..................................142–7
Prolonged Inrush Currents With Parallel Transformers Affect Differential Relaying. Hayward.................1096–1101; disc. 1305
Protection Against Conductor Burndown From That Cause, Power Arc-Over on Overhead Distribution Lines and Newly Developed Equipment for. Matthews......596–604; disc. 684
Protection for Transmission Lines and Distribution Feeders, Sensitive Ground. Gross....968–71
Protection, Harmonic-Current-Restrained Relays for Transformer Differential. Hayward..........................377–82; disc. 622
Protection Independent of Current-Transformer Characteristics, Bus. Steeb..859–62; disc. 1365
Protection, New Current Transformer for Bus Differential. Kennedy, Sinks...1180–7; disc. 1363
Protection of Low-Voltage Circuits by Air Circuit Breakers in Cascade Arrangement. Anderson, Black...............1151–60; disc. 1356
Protection of Medium-Voltage Lines, Minimum Insulation Level for Lightning. Ekvall..........................128–32; disc. 719
Protection of Power Transformers Against Lightning Surges. (Committee Report)..........................568–77; disc. 749
Protection of Single-Phase Motors, The Inherent Overheating. Potter.......993–6; disc. 1400
Protection of Solid Insulation by Lightning Arresters, The. MacCarthy, Carpenter..........................912–15; disc. 1349
Protection of Stations, Development in Lightning. Whitehead................898–900; disc. 1372
Protection on Transmission Lines, Experience With Preventive Lightning. Waldorf..........................249–54; disc. 701
(Protective Devices) A Conserved-Pressure Air-Blast Circuit Breaker for High-Voltage Service. Rankin, Bennett...193–7; disc. 673
(Protective Devices) A Double-Break Oil- or Gas-Blast Power Fuse. Hill.....402–07; disc. 646
(Protective Devices) A High-Power Oilless Circuit Interrupter Using Water. Leeds..85–88; disc. 625
(Protective Devices) A New Air Circuit Breaker With 250,000-Kva Interrupting Capacity. Dickinson, Nau............197–201; disc. 671
(Protective Devices) A New Current-Limiting Fuse. Rawlins, Strom, Graybill..........................77–80; disc. 657
(Protective Devices) A Novel Reclosing Relay. Bobo....................1041–5; disc. 1403
(Protective Devices) A Simple Method for Determination of Ratio Error and Phase Angle in Current Transformers. Wentz..........................949–54; disc. 1369
(Protective Devices) A Vertical-Flow Outdoor Compressed-Air Breaker. Ludwig, Baker..........................217–22; disc. 672
(Protective Devices) An Automatically Reclosing Breaker for Co-ordinating Distribution Systems. Rawlins, Wallace............1021–4
(Protective Devices) An Improved A-C Pilot-Wire Relay. Neher, McConnell...12–17; disc. 638
(Protective Devices) An Improved Polyphase Directional Relay. Hoard....246–8; disc. 681
(Protective Devices) Control of the Switching Surge Voltages Produced by the Current-Limiting Power Fuse. Williams, Schuck..........................214–17; disc. 678
(Protective Devices) Criteria for Neutral Stability of Wye-Grounded-Primary Broken-Delta-Secondary Transformer Circuits. Shott, Peterson................997–1002; disc. 1394
(Protective Devices) Dielectric Strength of Oil for High-Voltage Testing of Oil Circuit Breakers. Lingal, Skeats, Braley................903–06
(Protective Devices) Dielectric Strength of Water in Relation to Use in Circuit Interrupters. Slepian, Denault, Strom.....389–95; disc. 631
(Protective Devices) D-C Machine Flashover and Bus Short-Circuit Protection. Montgomery, Sellers..................1168–73; disc. 1370
(Protective Devices) Displacement and Diffusion in Fluid-Flow Arc Extinction. Slepian..........................162–7; disc. 643
(Protective Devices) Factors Contributing to Improving Electric Service by Means of High-Speed Switching and Utilization of Stored Energy. Logan, Miles....1012–16; disc. 1408
(Protective Devices) Field Investigations of Lightning. Wagner, McCann, Beck..........................1222–30; disc. 1381
(Protective Devices) High-Voltage Bushings Designed to Meet Modern Service. Brandt, Rorden.....................255–60; disc. 696
(Protective Devices) Lightning to the Empire State Building. McEachron....885–90; disc. 1377
(Protective Devices) Line-Type Lightning-Arrester Performance Characteristics. (Committee Report)..........................982–3
(Protective Devices) Mechanical Simplicity of Air-Blast Circuit Breakers. Haberl, Jensen..........................869–74; disc. 1355
(Protective Devices) Medium-Capacity Air-Blast Circuit Breakers for Metal-Clad Switchgear. Bennett, Wyman..............383–8; disc. 627
(Protective Devices) Modern Relaying for A-C Secondary Network Systems. Beeman..........................237–41; disc. 683
(Protective Devices) Photographic Study of A-C Arcs in Flowing Liquids. Slepian, Browne..........................823–8; disc. 1330
(Protective Devices) Possibilities and Methods of Extending a Carrier Current Relay Channel to Other Uses. Smith, Goldsborough..........................23–7; disc. 645
(Protective Devices) Power-Circuit-Breaker Ratings. Van Sickle............882–4; disc. 1353
(Protective Devices) Prolonged Inrush Currents With Parallel Transformers Affect Differential Relaying. Hayward....1096–1101; disc. 1305
(Protective Devices) Report on Apparatus Bushings. (Committee Report).....266; disc. 695
(Protective Devices) Surges on Chicago 12-Kv System. Wollaston, Plumley...260–5; disc. 694
(Protective Devices) System Short-Circuit Currents. Hanna, Travers, Wagner, Woodrow, Skeats..................877–81; disc. 1351
(Protective Devices) The Geometry of Arc Interruption. Boehne...........524–32; disc. 675
(Protective Devices) The Recovery-Voltage Analyzer for Determination of Circuit Recovery Characteristics. Dunlap...958–62; disc. 1391
(Protective Devices) Vertical-Flow Interrupter and Its Application to "Oil-Poor" Circuit Breakers, The. Baker................440–5; disc. 635
Protective Link, The. Hodnette, Leonard..........................226–9; disc. 679
Pump Motors, Some Acceleration Tests on Large Synchronous. Ager.........416–22; disc. 649
Push-Button-Tuned 50-Kw Broadcast Transmitter, A. Rockwell, Lepple...............1–3

Q

Quality, Impulse Strength as a Measure of Cable. Komives..................929–34; disc. 1339
Quantities, The Determination of Magnitude and Phase Angle of Electrical. Walker..........................837–9; disc. 1333
Quantity Production, High-Potential Testing Equipment for. Summers...289–92; disc. 756
Quietness, Some Insulator Designs Require Special Features to Insure Radio. Miller..........................62–6; disc. 657

R

Radiant Heat—A Full-Fledged Industrial Tool. Goodell..........................464–71
Radio Interference, Aircraft Precipitation-Static. Starr..........................363–70
Radio Quietness, Some Insulator Designs Require Special Features to Insure. Miller..........................62–6; disc. 657
Radiobroadcasting in Canada. Frigon..........................896–8; disc. 1357
Railroad Trains, The Application of Electricity for the Auxiliaries of. Gardner...34–6; disc. 632
Rating and Life of Cold-Cathode Tubes, Current. Rockwood................901–03; disc. 1390
Rating of Arc-Welding Generators and Transformers, The Service Factor. Freeman, Welch......................137–41; disc. 726
Ratings and Applications, Classification and Co-ordination of Short-Time and Intermittent. Hellmund...................792–8; disc. 1323
Ratings, Power-Circuit-Breaker. Van Sickle..........................882–4; disc. 1353
Ratio Control Transformers Operating in Parallel and in Networks, Operation of Load. Starr..........................1274–80; disc. 1407
Ratio Error and Phase Angle in Current Transformers, A Simple Method for Determination of. Wentz...............949–54; disc. 1369
REA Distribution Systems and Telephone Systems, Inductive Co-ordination of. Plucknett, Smith, Taylor......................586–95; disc. 723
Reclosing Breaker for Co-ordinating Distribution Systems, An Automatically. Rawlins, Wallace..............................1021–4
Reclosing of High-Voltage Transmission Lines, Five Years' Experience With Ultrahigh-Speed. Sporn, Muller...............241–6; disc. 690
Reclosing Relay, A Novel. Bobo..1041–5; disc. 1403
Recorder, Ampere-Squared-Second. Rich..839–42
Recovery-Voltage Analyzer for Determination of Circuit Recovery Characteristics, The. Dunlap....................958–62; disc. 1391
Rectangular Tubular Conductors, Formulas for the Inductance of. Higgins...1046–50; disc. 1408
Rectifier Corrosion Problem, The Water-Cooled Steel-Tank. Remscheid..... 173–8; disc. 753
Rectifier Installation, Alcoa. Housley, Winograd..........................1266–74; disc. 1409
Rectifiers, Excitation Circuits for Ignitron. Myers, Cox....................943–8; disc. 1358
Rectifiers for Traction Service, Glass-Bulb Mercury-Arc. Woolgar..............843–6; disc. 1383
Rectifying Circuits With Capacitance Filters, Diode. Waidelich..........1161–7; disc. 1388
Regulation and Control, A New Mercury Rheostatic Element for. Oplinger.....846–9; disc. 1386
Relative Accuracy of Three-Phase Metering Combinations. Weller..........925–9; disc. 1336
Relaxed Initial Conditions in Transient Problems, A New Method for Introducing. Johnson..........................178–81
Relay, A Novel Reclosing. Bobo..1041–5; disc. 1403
Relay, An Improve A-C Pilot-Wire. Neher, McConnell..................12–17; disc. 638
Relay, An Improved Polyphase Directional. Hoard......................246–8; disc. 681
Relay Channel to Other Uses, Possibilities and Methods of Extending a Carrier Current. Smith, Goldsborough..........23–7; disc. 645
Relay Literature—1927–1939, Bibliography of. (Committee Report)...............1435–47
Relaying for A-C Secondary Network Systems, Modern. Beeman..........237–41; disc. 683
Relaying, Prolonged Inrush Currents With Parallel Transformers Affect Differential. Hayward.................1096–1101; disc. 1305
Relays for Transformer Differential Protection, Harmonic-Current-Restrained. Hayward..........................377–82; disc. 622
(Relays) System Short-Circuit Currents. Hanna, Travers, Wagner, Woodrow, Skeats..........................877–81; disc 1351
Report of the Board of Directors..........1449–63
Report on Apparatus Bushings. (Committee Report)..........................266; disc. 695
Repulsion Motors, Performance Calculations on. Trickey......................67–73; disc. 661

Preface

This, the 60th volume of the Transactions of the American Institute of Electrical Engineers, contains all approved technical-program papers and related discussions presented during the calendar year 1941, and all previously unpublished papers and discussions presented in 1940. They were presented at the following AIEE conventions and District meetings:

1. 1940 summer convention, Swampscott, Mass., June 24–28: 17 papers and related discussion; 24 papers and related discussion were published in the 1940 volume.
2. 1940 Pacific Coast convention, Los Angeles, Calif., August 27–30.
3. Middle Eastern District meeting, Cincinnati, Ohio, October 9–11, 1940.
4. 1941 winter convention, Philadelphia, Pa., January 27–31.
5. North Eastern District meeting, Rochester, N. Y., April 30–May 2, 1941.
6. 1941 summer convention, Toronto, Ont., Can. June 16–20.
7. 1941 Pacific Coast convention, Yellowstone National Park, August 27–29.
8. South West District meeting, St. Louis, Mo., October 8–10, 1941.
9. Southern District meeting, New Orleans, La., December 3–5, 1941.

In addition this volume contains:

1. Report "Telemetering, Supervisory Control, and Associated Circuits," prepared by a joint subcommittee of the AIEE committees on automatic stations, and instruments and measurements.
2. "Bibliography of Relay Literature, 1927–1939," prepared by the relay subcommittee of the AIEE committee on protective devices.
3. Report "Standard Basic Impulse Insulation Levels," prepared by the joint committee on co-ordination of insulation of AIEE, Edison Electric Institute, and National Electrical Manufacturers Association.
4. 1941 annual report of the AIEE board of directors.
5. A complete listing of AIEE officers and committees for 1941–42.

Under the present publication policy a large proportion of the content of this volume was given advance publication in the Transactions Sections of the monthly issues of Electrical Engineering during 1941, and extra sheets were printed at the same time for binding in this volume. The papers so published comprise pages 1–312 and 763–1050, inclusive; pages 313–762 and 1051–1410, inclusive, did not appear in Electrical Engineering, but were given advance publication in the June and December 1941 "Supplements to Electrical Engineering—Transactions Section," respectively.

Full correlation of all material in this volume has been accomplished through the medium of the multientry reference index beginning on page 1469. A reference to any of the several subject entries for any technical paper will lead directly to the paper and to any published discussion on that paper.

Statements and opinions given in papers and discussions published in Transactions are the expressions of contributors for which the American Institute of Electrical Engineers assumes no responsibility.

Errata

1. Page 114. Illustration designated Figure 3 should be Figure 4; illustration designated Figure 4 should be Figure 3.

Page 194, column 1, line 5. The statement ". . . at 38 kv . . ." should read ". . . at 88 kv . . ."

3. Page 194, Figure 4. The ordinate scale now reads $KVA = \frac{EI}{1000}$; should read $\frac{KVA}{1000}$.

4. Page 194, column 3, line 22. The word "minimum" should read "maximum."

A Push-Button-Tuned 50-Kw Broadcast Transmitter

R. J. ROCKWELL
NONMEMBER AIEE

H. LEPPLE
NONMEMBER AIEE

Synopsis: This paper describes the use of automatic push-button tuning on short-wave broadcast transmitters that are required to change from one frequency to another with the least possible interruption to programs. The tuning control circuits and the arrangement of the radio-frequency circuits of the transmitter are described.

THE effective use of high frequencies for international radiobroadcasting requires the transmitter to use a frequency which will place the strongest signal in the selected service area. Since the best frequency to use will vary throughout the day, and since it may be desirable to shift the signal from one area to another, a transmitter built for international broadcasting should be able to change frequencies easily and rapidly.

Ordinarily a shutdown period is necessary to retune the transmitter whenever the frequency is changed. In the past when it has been necessary to change frequencies rapidly, as for instance during the short interval between programs, it has been customary to use a second transmitter tuned to the new frequency and then shift transmitters. This cumbersome procedure can be avoided if the tuning process is speeded up by the use of automatic devices. Retuning the transmitter is then a matter of seconds and is accomplished by simply pushing a button.

Description of Transmitter

The 50-kw WLWO transmitter of The Crosley Corporation employs automatic push-button tuning and a description of this transmitter will illustrate the practicality of this method of tuning.

The transmitter is designed to operate on any one of eight different frequencies. Figure 1 is a circuit diagram of the radio-frequency section of this transmitter. The radio-frequency amplifier up to and including the one-kilowatt stage is mounted on one chassis. Since the coils and capacitors for the grid and plate circuits of these stages are small, a separate set of coils and capacitors is used for each frequency. These coils and capacitors are mounted on a drum which is rotated by a motor until the proper tuned circuits make contact with a set of fixed wipers. The eight crystals are mounted separately and are kept at operating temperature at all times. When the drum rotates to bring into position the coils for a particular frequency, it also makes connection to the crystal for that frequency.

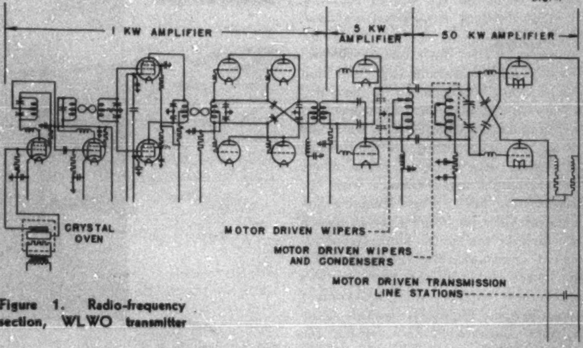

Figure 1. Radio-frequency section, WLWO transmitter

The plate coil of the 5-kw stage and grid coil of the 50-kw stage are too large to employ the preceding method of tuning. These circuits are tuned, therefore, by means of motor-driven wipers mounted on a shaft which runs through the center of the coil. The shaft is arranged to rotate the wipers in opposite directions. As the shaft turns the wipers slide along the turns of the coil, traveling from the middle toward each end. The wipers short-circuit a certain number of turns of the coil depending upon the frequency to be used. Figure 2 is a picture of the plate coil of the 5-kw stage. The rotating drum and the wipers on both the 5-kw tank circuit and the 50-kw grid circuit in addition to being motor driven may be rotated by a hand wheel mounted on the front of the transmitter cabinets. This arrangement is necessary to adjust the tuning system as described later in this paper.

The 50-kw amplifier employs a transmission-line tank circuit. This trans-

Figure 2. Five-kw tank coil

Paper 40-161, recommended by the AIEE committee on communication, and presented at the AIEE Middle Eastern District meeting, Cincinnati, Ohio, October 9–11, 1940. Manuscript submitted August 12, 1940; made available for preprinting September 10, 1940.

R. J. Rockwell, member IRE, and H. Lepple, associate member IRE are with WLW, Crosley Radio Corporation, Cincinnati, Ohio.

Figure 3. Transmission-line station

mission line is designed to present the proper load impedance to the final amplifier and also couple the antenna load to the transmitter. This is accomplished by switching across the transmission line at the proper point a capacitor of such size as to obtain the desired coupling. If eight different frequencies are used, there will be eight stations along the transmission line. Each station will consist of a group of vacuum capacitors that can be swung into contact with the transmission line by a motor. The capacitors are mounted on Mycalex arms which are swung from a horizontal position through 90 degrees to a vertical position where the capacitors make contact with the transmission line. When changing frequencies, the capacitors for the frequency on which the transmitter has been operating will swing away from the transmission line at the same time that the capacitors for the new frequency swing into contact with the line. Figure 3 is a picture of the WLWO transmission line showing the capacitor stations.

In addition to tuning the various tank circuits, it is necessary to match the antenna to the transmission line for each frequency. The circuits necessary for doing this are brought to contacts mounted on Mycalex plates. Wipers are rotated by a motor to select the circuits for the frequency to be used. Figure 4 shows the method of mounting these coils and the selecting mechanism. A portion of the coils have been removed to simplify the picture. This equipment is located in the antenna coupling house, some 200 yards from the transmitter building.

Tuning Control Circuits

From the preceding description it is evident that five operations must be completed to retune the transmitter. The drum on the 1-kw chassis must rotate to the proper set of coils, the wipers on the 5-kw tank coil and the wipers on the grid coil of the 50-kw stage must each move to a new position, a different capacitor station along the transmission line must swing into position, and the antenna must be matched to the transmission line.

Figure 4. Antenna matching mechanism

Each of these operations, except the tuning of the transmission line, is carried out by a rotating drum, a rotating switch, or a rotating wiper. The problem is to control these rotating devices so that they will turn through the shortest path to their new position and stop. To do this, three-phase motors and the motor-reversing circuit illustrated in figure 5 were used. *D* is a bakelite disk mounted on a shaft which is mechanically connected to the rotating drum or wiper arms. This disk has a pin protruding from its side which engages the switch arm as shown in the diagram. If this disk is turned clockwise the switch arm will take the position shown in *A* and the circuit will be completed through the upper spring contact to relay number 2. However, if the disk is turned counterclockwise, as shown in *B*, relay number 1 will be operated and the motor will be reversed.

If the disk is in position *A* when the switch in P_1 is closed, relay number 2 will operate and the motor, being connected to rotate the disk counterclockwise will turn the disk until it is in position *C* when the relay will be released and the motor will stop. Likewise, when the disk is in position *B* when P_1 is closed, the motor will rotate in the reverse direction turning the disk clockwise until position *C* is reached.

If it is desired to have the motor stop at any one of eight positions, eight of these disks will have to be mounted on the shaft. For eight positions the circuit will be as shown in figure 6. Each of the eight "disk-switches" will make connection to either relay number 1 or number 2 depending upon whether the wiper will have to rotate clockwise or counterclockwise to reach its position. To select one of the eight positions it is only neces-

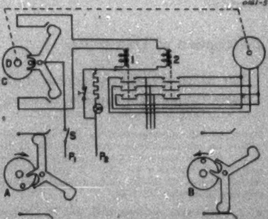

Figure 5. Tuning-motor reversing circuit

sary to close one of the eight switches S_1 through S_8, figure 6.

In applying the above system to WLWO it was necessary to control four motors in the above manner. To do this the circuit shown in figure 7 was devised. Eight frequency-selecting relays replace the switches S_1 through S_8 of figure 6. Each relay has a normally open contact for each of the motors that is to be controlled, that is, four normally open contacts. For simplicity only one tuning index and one transmission line station is shown connected in figure 7. The three tuning motors and the seven transmission line stations that are not shown are connected to the remaining normally open contacts in a similar manner. Each of the frequency relays may be "locked in" by pressing the proper frequency button as shown in figure 7. When one of these relays is "locked in", one of the disk-switches on each of the four motor index systems is energized and each of the four motors will rotate to its position and stop. It will be noted in figure 7 that the push buttons and the relay holding circuits are designed so that when a relay is "locked in" by pressing one of the buttons, the relay previously "locked in" is released. This arrangement makes it unnecessary to use an off button to release the previous frequency.

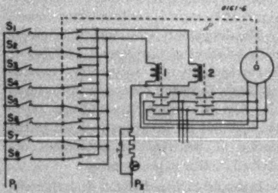

Figure 6. Eight-position motor control circuit

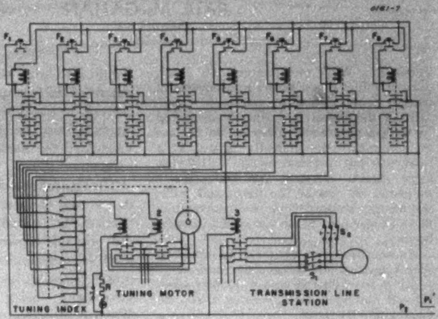
Figure 7 also shows the control circuits for the transmission line stations. Relay number 3 is used to reverse the motor phases. When this relay is not energized the phases are connected to rotate the capacitors away from the transmission line. A limit switch operated by a cam on the rotating capacitor arms stops the motor. When the relay is energized the motor is connected to swing the capacitors into contact with the transmission line and again the motor is stopped by a limit switch. Each motor is equipped with a magnetic brake which is needed to bring the motor to a quick stop after the power is disconnected.

Figure 7. Push-button-tuning circuit



Adjusting the Tuning System

Referring to figure 5 it will be seen that a resistor and a six-volt bulb are connected in P_2 of the relay circuit. A switch is shown short-circuiting the bulb and resistor. If this switch is opened and the "disk-switch" is in either position A or B the lamp will burn but the relay will not pull in because of the voltage drop across the lamp and resistor. If the disk is turned the lamp will go out when position C is reached. The bakelite disks shown in figure 5 are held by friction to the shaft which is connected to the wipers and are arranged so that they will slip when turned by hand.

The procedure for adjusting the tuning system is as follows: First, the short-circuiting switch is opened and one of the frequency buttons is pressed to lock in one of the frequency relays. Next, the transmitter is tuned manually. This is done by rotating the wipers by hand, using the hand wheels provided for this purpose, until resonance is reached. Then, the bakelite disk is rotated, slipping on its shaft while the wiper arms are held stationary, until the light goes out. The short-circuiting switch is then closed and the transmitter is ready to tune automatically to this frequency. The same procedure must be followed for each tuning motor and for each frequency. A different push button and its associated "disk-switch" will be used for each frequency. After each of the tuned circuits is adjusted as just described, the entire transmitter will retune to any one of the eight frequencies by simply pressing the proper button.

An Improved Type of D-C Wattmeter of the Shunted Type

PAUL MacGAHAN
MEMBER AIEE

Synopsis: While wattmeters for high current values of a-c power are universally used in connection with instrument transformers, d-c power is ordinarily measured by using separate ammeters and voltmeters on account of the difficulty in making a heavy-current d-c wattmeter. Although large direct currents are conveniently measured by use of the shunt and millivoltmeter, shunted-type d-c wattmeters have in the past been somewhat unsatisfactory.

An improved d-c wattmeter is described which corresponds in accuracy and sensitivity to the usual permanent-magnet moving-coil ammeter and operates from the usual ammeter shunt.

THE measurement of power in a d-c circuit is generally accomplished by the use of separate ammeters and voltmeters. This has been acceptable for most d-c conditions because a simple multiplication of amperes and volts gives the correct power. Furthermore, the construction of a direct-reading d-c wattmeter for large currents has heretofore involved great difficulties in construction and installation.

In certain cases where the voltage is variable, it would be distinctly preferable to read the watts directly. The instrument described is designed to fill this need.

D-c wattmeters for low values of current can be satisfactorily designed using the electrodynamic principle with a stationary coil carrying the entire current and a moving coil in the voltage circuit. The practical limitations of this construction are due to the difficulty in constructing the series coil for currents in excess of about 400 amperes capacity, as well as the matter of the heavy and expensive leads required to bring the current to the terminals of the instrument. A minor difficulty is to avoid residual magnetization errors because the heavy currents tend to magnetize the metal cases and internal magnetic shields.

The reason these difficulties do not exist in the case of measuring d-c amperes is because the permanent-magnet moving-coil principle requires a very low power level of operation, compared with the power taken by instrument coils of any instrument using other principles. Whereas an ordinary portable or switchboard-type electrodynamic wattmeter without iron cores requires a power level of the order of one or two watts to energize the current coil, the coils of corresponding permanent-magnet moving-coil movements of normal sensitivity take only 0.0004 watt and when one of the newer types of high coercive magnet steel is used, the power level may be much less.

It is this unique quality of the permanent-magnet moving-coil type instruments[1] which permits their use as shunted ammeters, with shunts having the usual standard drop of only 50 millivolts. In order to make a shunted-type coreless electrodynamic wattmeter for 10,000 amperes with the same ratio of copper to swamping resistance, and consequently the same temperature error as in the d'Arsonval ammeter, would require a shunt consuming at least five or six kilowatts.

It is not unusual to mount instruments on switchboards, 50 or more feet from the bus-bar structure. Such long leads still further increase the resistance, and consequently, the power required in the shunt.[2]

Another difficulty attending attempts to operate such wattmeters from ammeter shunts is that in order to obtain a sufficiently large current in the shunted-coil circuit, the resistance of the coil and of the leads must be made very low. Thus, any contact resistance in the connections introduces a variable which causes a considerable error in the readings.

However, such shunted-type electrodynamic wattmeters have been built, generally by the expedients of reducing the ampere turns of the series coils to subnormal values and obtaining a torque subnormal in value but yet sufficient to operate the movement by working the voltage coils much harder in proportion. This involves considerable compromise in the direction of allowing much higher temperature errors in both the moving-coil and current-coil circuits. The constants of one wattmeter of this construction are shown in column *A* of table I. Such designs can be regarded only as compromises.

The desirability of finding other means as a solution of the general problem of heavy-capacity d-c wattmeters became apparent from the data given in column *A*. Several other possibilities were studied and the investigations led to the design of the type of instrument described further in this paper.

It should be noted that a desirable element of the problem from an economic viewpoint was the necessity of utilizing to as great extent as possible, existing instrument mechanisms, because the probable applications are not so large as are those of other instruments; moreover, commercial instruments can be built economically only with the aid of expensive tool equipment. Uniformity in appearance with other switchboard instruments was another desideratum.

These considerations led to the belief that the most practical solution might lie in substituting an iron-core electromagnet for the usual permanent magnet of the

Table I. Constants Compared

	(A) Shunted Electrodynamic Wattmeter Without Iron Core	(B) Shunted Iron-Cored Wattmeter
Voltage-coil circuit (460 volts)		
Total resistance (ohms)	13,000	4,350
Resistance, copper coil (ohms)	65	375
Ratio, copper to total resistance	0.005	0.086
Current-coil circuit		
Resistance, current coil (ohms)	0.0055	0.27
Resistance, two shunt leads (ohms)	0.0073	0.12
Resistance, springs (ohms)		0.44
Swamping resistance* (ohms)	0.02	2.12
Total resistance, shunted current circuit (ohms)	0.0328	2.95
Current-circuit copper ratio	0.39	0.17
Full-scale current in coil (amperes)	6.2	0.017
Length, pair of leads (feet)	120.0	120.0
Cross section, leads (square centimeters)	157,380.0	9,700.0
Approximate cost of leads, compared with cost of instrument (per cent)	300	5
Full-load millivolts at shunt (per cent)	200	50
Full-load watts in shunt (10,000 amperes) (per cent)	2,000	500
Temperature influence† (per cent)	1.08	0.4
Weight of moving element (grams)	2.8	1.4
Full-scale torque (millimeter grams)	1.3	1.7
T/W ratio	0.46	1.2
Residual error by reversing polarity of current circuit (per cent)	2.0	0

* Low temperature coefficient wire in series with coil.

† Includes voltage and current circuit and effect of springs.

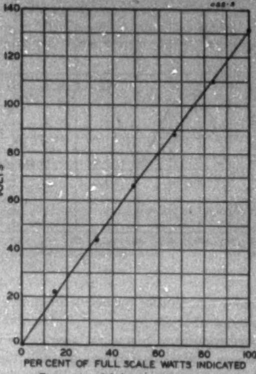

Figure 3. Voltage-error curve

Variable voltage, constant millivolts (amperes); average of increasing and decreasing voltage readings

conventional d-c ammeter, and winding the stationary coils of the electromagnet for excitation from the voltage of the circuit to be measured. This would bring the power-level requirement of the moving-coil circuit down to that of the permanent-magnet moving-coil type, thereby avoiding the difficulties exemplified in column *A* of table I. The problem of eliminating the residual magnetizing errors due to the usual iron-cored magnetic circuit remained to be solved before a commercially satisfactory instrument could be obtained.

Soon after the original development by Doctor Yensen[4] of the low-loss, low-residual forms of iron known as Hipernik, certain designers succeeded in greatly improving the accuracy of moving-iron ammeters or voltmeters for direct current by using this material for the vanes.

Hipernik is characterized by the almost total absence of magnetic coercive force. As indicated in the hysteresis curve, figure 1, the coercive field is of the low value of 0.04 to 0.06 oersted. As a comparison, the following values may be noted for other forms of steel or iron.

Cold rolled steel, annealed	2.0 oersteds
Armco (a very pure low-carbon steel)	1.0 oersted
Silicon steel	0.32 to 0.85 oersted

In the instrument herein described, use is made of nearly all the usual parts of the corresponding size d-c permanent-magnet moving-coil ammeter, with the exception that an electromagnet is used instead of the permanent magnet. The shape of the electromagnet is so designed as to be assembled in the place of the usual permanent magnet. Hipernik is used for the electromagnet core and also instead of the soft-iron pole pieces and cylindrical core ordinarily used in ammeters or voltmeters. The Hipernik is further annealed in hydrogen at 1,200 degrees centigrade after being machined. The moving element, complete with windings, pointer, springs, and swamping resistance, is exactly the same as that used in the ammeters.

By using the same flux density in the electromagnet as in a permanent magnet, the sensitivity of the current element is made approximately the same as that of the ammeter. This permits the use of the instrument in connection with the usual ammeter shunt, with the same conditions as to length of leads, temperature error compensation, and mechanical action. The ratio of torque to weight, and thus the "figure of merit," is also the same.[5]

The flux density for the working limits of voltage variation in the circuits on which the wattmeter is intended is chosen to correspond with the straightest portion of the magnetization curve of the Hipernik as shown in figure 2. This and the presence of the air gap result in the voltage influence being reduced to a minimum. Figure 3 shows the actual voltage errors of the instrument. The curve is drawn to the average of the ascending and descending values so as to distinguish from the residual errors.

The temperature error of the voltage circuit is reduced to permissible limits by the use of an external resistor of the usual low-temperature-coefficient type such as manganin, constantin, or similar alloy wire.

As in the permanent-magnet moving-coil type, the damping of the instrument is due to the eddy currents generated in the aluminum frame on which the moving coil is wound. As the flux varies with the voltages, the damping effect also varies but is so proportioned as to give the best damping at the average operating voltage. Thus the instrument is inclined to be overdamped at higher voltages and underdamped at low voltages. This, however, is not

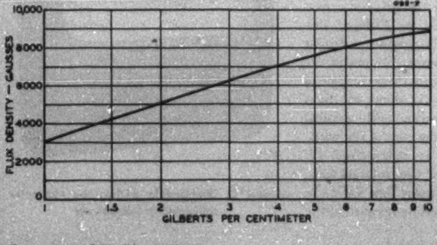

Figure 2. Magnetization curve for Hipernik

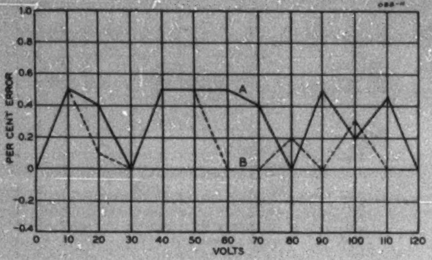

Figure 4. Residual errors—varying voltages, amperes constant

A—Normal polarity
B—Reverse polarity

wholly undesirable, because less damping is required at the lower parts of the scale corresponding in general to lower applied voltage and loads. Where desired, the damping can be increased readily by the well-known method of shunting the entire moving element by a stationary resistance coil. This is, however, at the expense of a corresponding increase of current in the leads which connect the instrument to the shunt.

Figure 4*A* shows the actual residual errors of the instrument on descending values of voltage, the ascending values being used as standard. Figure 4*B* is similar to figure 4*A* except that the polarities have been reversed. It should be noted that there are no residual errors due to variations or reversal of direction of the applied current. Voltage variations are, of course, less extreme in practice than current variations.

A further reduction in the over-all residual error to a value of plus or minus one-fourth per cent is possible by using the average of the increasing and decreasing voltage readings in calibrating the instrument. As errors of this order are less than the usual errors of temperature, friction, and scale marking in the ordinary high-grade switchboard instruments, the residual errors may be disregarded for practical purposes.

The polarity of the voltage does not ordinarily reverse in the course of the normal operation of a wattmeter and the terminals are marked for connection to a definite polarity as used for calibration. This is to avoid the slight additional residual error which would occur from reversal of the electromagnet flux.

It will be noted from the residual-error curve that this effect is not entirely eliminated at all parts of the voltage cycle. However, the performance in this respect compares very favorably with that of the best moving-iron ammeters or voltmeters and is considerably better than in the electrodynamic type described previously.

The completed instrument is shown in figure 5. A similar instrument of the rectangular type, with the scale calibrated in horsepower, is illustrated in figure 6. Figure 7 shows the internal construction of the instrument.

The constants and data of this new d-c wattmeter are given in column *B* of table I. In order to allow a direct comparison with the electrodynamic type d-c wattmeter, column *A*, an instrument of the same capacity and for the same length of leads, is tabulated.

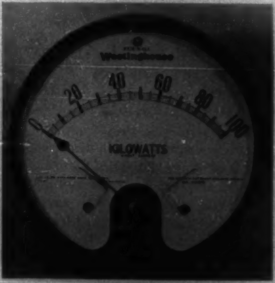

Figure 5. Round-pattern d-c wattmeter calibrated in kilowatts

While the instrument described in this paper is of the indicating switchboard type, satisfactory d-c recording or portable wattmeters could be built on the same principle.

A further study of the prior art, particularly as practiced in Europe, disclosed the existence of somewhat similar d-c iron-cored wattmeters. In one of the wattmeters described in these European references,[6,7] a magnetic shunt of high-coercive material is permanently applied to the pole pieces of the core of the wattmeter. This shunt is magnetized directly by the field of the voltage coils. As the voltage and main flux varies, a compensating effect results because of the high remanence of the shunting member which produces a remanent flux through the air gap. The strength and polarity of this remanent flux depend upon the previous magnetic condition of the electromagnet. Since this flux is of the opposite polarity to that of the residual magnetization of the core itself, the residual errors are reduced. During the course of development, this construction was tried, but the experiments failed to produce a satisfactory result.

Another form described in the above reference (Keinath, page 284) depends upon the use of a very short magnetic circuit instead of a compensating element, but the performance curves given show considerable residual error, because a nonresidual magnetic material, such as Hipernik was not available.

Application

In general, it is more desirable to indicate the power directly on a dial than to determine the power by simultaneous voltmeter and ammeter readings. This may even be the case where the voltage is fairly constant. But the more important application of the d-c wattmeter is to circuits in which the voltage varies between wide limits, either purposely for speed- or power-control reasons, or because of circuit conditions. The well-known "variable-voltage control," as introduced originally by H. Ward Leonard[2,3] is a typical example.

In this system, the speed of a motor is controlled by varying the voltage across its armature. This is accomplished by changing the field excitation and consequently the voltage of the generator which drives the motor, thus avoiding the losses and other disadvantages of direct rheostatic speed control.

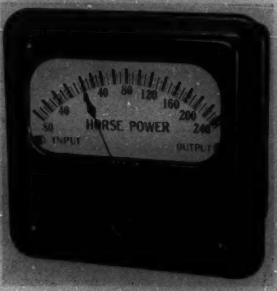

Figure 6. Rectangular-pattern d-c wattmeter calibrated in horsepower

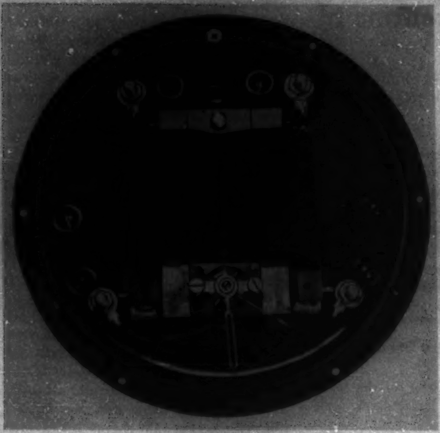

Figure 7. Internal view of d-c wattmeter

When such speed or power control is applied to certain functions, such as harbor dredges or other marine power equipment, it is important to have a direct indication of power at the switchboard or control station.

Another actual application is to power indication of electric dynamometer load sets for production testing of internal-combustion engines. On such applications it is generally preferred to calibrate the scale to read directly in horsepower instead of in kilowatts. The instrument illustrated in figure 6 was specially intended for this purpose.

Discussion

Discussion will be found in the 1941 annual Transactions volume and in the June 1941 Supplement to Electrical Engineering—Transactions Section.

Some Characteristics and Applications of Negative-Glow Lamps

H. M. FERREE
ASSOCIATE AIEE

THE glow lamp is a modern electrical device employing the peculiar properties of various rare gases which when energized by the application of a voltage ionize and pass current. This ionization is accompanied by the production of light.

It has long been known that if sufficiently high voltage is applied to electrodes that are sealed within a bulb containing an inert gas (neon, for example) at the proper pressure, light is produced at the negative electrode or cathode. For this reason, glow lamps are sometimes called "negative-glow lamps" since all the glow takes place at the negative electrode. This is evident on direct current, but on alternating current the reversal of polarity is so rapid that both electrodes appear to glow.

This phenomenon, until recently, was always associated with high voltage. During recent years, however, methods have been developed for so sensitizing electrode surfaces that the voltage for initiating and maintaining a discharge in these rare gases has been reduced to as low as 60 volts on direct current and about 42 volts on alternating current.

Glow Lamps as Light-Producing Devices

With the advent of low-voltage lamps the use of glow lamps on commercial lighting circuits became practical. Various sizes and types of glow lamps are now commercially available ranging from about 0.25 watt to 3 watts in power consumption.

Neon, as used in glow lamps, has proved to be the most efficient of the rare gases as a light-producing medium. In standard commercial glow lamps the light output is about 0.025 candlepower per milliampere. Their normal brightness is approximately 0.8 candlepower per square inch of sensitized electrode surface.

Since the light output of glow lamps is not great, they of course find only limited use as sources of illumination; they are valuable, however, as signals, pilots, and indicators of the presence of potential and the consequent condition of the device to which this potential is applied.

Why Glow Lamps Are Used

There are many reasons for the selection of glow lamps for innumerable uses. Chief among these reasons are:

1. Low current consumption
2. Insignificant heat
3. Reliability
4. Long life
5. Wide voltage range
6. Ruggedness

The low current consumption is indicated by the current range which is from only 0.002 ampere for the smallest to 0.030 ampere for the largest lamp as now manufactured.

It is apparent that the amount of heat generated at the low wattages that glow lamps consume is insignificant.

These lamps are extremely dependable. Unlike other lamps, they do not suddenly fail at the end of some definite period, but rather, slowly decrease in light output during a period of some 3,000 hours. During this time, slow disintegration causes the walls of the bulb gradually to darken, and this is accompanied by an increasing cathode drop, so that after 3,000 hours use the light output has dropped to 70 per cent of its initial value.

This process continues until the lamp is no longer useful as a light-giving device. Unless the lamps are broken or subjected to a mechanical shock sufficiently violent to short-circuit the electrodes, they will not suddenly fail. This reliability recommends them for many unusual uses.

Voltage

Glow lamps are not affected by voltage variations to the same degree as filament lamps. Their light output varies in almost direct proportion to the current, while life varies, roughly, inversely as the square of the current. It is therefore apparent that ordinary fluctuations experienced on commercial circuits will have but a small influence on either the life or light output.

There are three separate and distinct voltages to be considered when discussing glow lamp voltage, namely:

1. Breakdown
2. Maintaining
3. Supply

Breakdown voltage is that voltage at which the gas becomes ionized and begins to pass current. Below this voltage the lamp cannot be made to light and will not pass current.

Maintaining voltage is the voltage at which the lamp will remain lighted after having started. On alternating current the maintaining voltage is practically the same as the breakdown voltage, while on direct current it is approximately 15 volts lower. There is, therefore, a considerable difference between the supply voltage and that at which the lamp will maintain. This difference is absorbed by a ballast resistor which serves to stabilize the lamp.

Volt-Ampere Characteristics

All gaseous-conduction lamps, of which the glow lamp is one, have a negative or "run away" characteristic. Because of this characteristic, if the lamp were connected directly across a source of voltage sufficiently high to ionize the gas, the current would immediately rise to such proportions as to destroy the lamp. It is

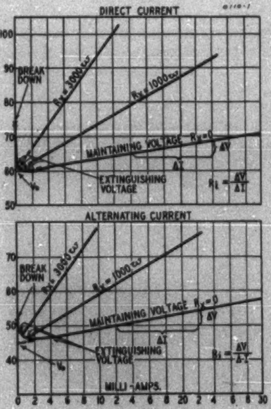

Figure 1. Characteristics of average S-14 two-watt lamp

Paper 40-110, recommended by the AIEE committee on production and application of light, and presented at the AIEE summer convention, Swampscott, Mass., June 24–28, 1940. Manuscript submitted January 28, 1940; made available for preprinting May 28, 1940.

H. M. Ferree is engineer in the lamp department of the General Electric Company, Cleveland, Ohio.

The author gratefully acknowledges the valuable contributions made by T. E. Foulke.

therefore essential that a limiting resistance be used in series with the lamp. In all lamps referred to here the resistor is built into the base. (See table III.)

The Electrical Characteristics of Negative-Glow Lamps

The negative-glow lamp, when carrying current, can be treated in an electrical circuit as the equivalent of a counter electromotive force with an internal resistance.

Thus for the purpose of calculation, the following symbols can be used:

Let

V = applied voltage
V_0 = the counter electromotive force
R_i = the internal resistance
R_x = the external resistance
I = the current in amperes

Note: R_x = the sum of all resistance outside of the lamp bulb and includes the resistance placed in the base, the resistance of the supply circuit, the meters used in testing, etc.

Then, the current in amperes is:

$$I = \frac{V - V_0}{R_i + R_x}$$

V_0 can accurately be determined from volt-ampere characteristics as the voltage at which the current is reduced to zero, but is approximately given by the minimum maintaining voltage or extinguishing voltage on either alternating current or direct current.

The internal resistance is mainly a function of electrode size, and secondly of the gas composition, pressure, and electrode construction. The exact value can be determined from the quotient of the change in maintaining voltage with corresponding change in discharge current. The a-c internal resistance is somewhat higher than d-c internal resistance, due to the high electrostatic capacity of the discharge in the cathode fall.

Before discharge occurs, that is, at voltages insufficient to cause breakdown, the lamp can be treated as a very high resistance and capacitance.

The Constants of Negative-Glow Lamps

Average values of the constants measured on standard a-c d-c neon glow lamps are included in table I. The external resistance indicated is the value to be used in series with the lamp to secure normal current at the specified alternating voltage. This is the resistance that is placed in lamps based with medium or candelabra screw bases.

A complete characteristic curve is shown and the graphical method of determining the constants of glow devices in figure 1.

Nonresistance Lamps

For some special uses, glow lamps are required without the resistance in the base. Lamps of this type are supplied mounted in double-contact bayonet bases, or bases of such design that they cannot be put into screw sockets, normally used on commercial circuits. With these lamps, it is necessary to use an external series resistor of a value equal to that normally built into the base of the corresponding lamp (see table III), or to operate these lamps in circuits whose natural impedance is sufficient to limit the lamp current to normal values.

Improper application of nonresistance lamps will result in the violent destruction of the lamp.

Glow lamps may be used on voltages many times greater than their normal rating, provided sufficient additional external resistance is used in series with the lamp. The proper value of external resistance to be used with standard lamps on various voltages is shown in table II, together with the proper wattage rating for the resistor. The wattage rating shown is in accordance with accepted practice for cool operation when used in enclosed devices. If used in open circulating air, a rating of approximately one-fourth these wattage ratings may be used.

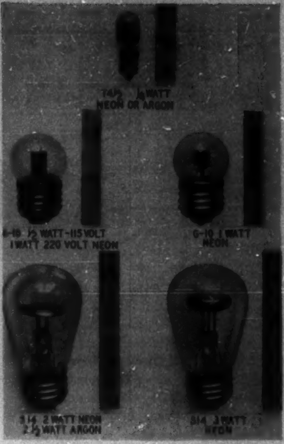

Figure 2

Example. If a one-quarter-watt 115-volt lamp is to be built into a housing or enclosure, and operated on a 300-volt circuit, the table indicates the use of a 93,000-ohm 1.5-watt resistor. However, if used in open air, a 0.5-watt resistor will suffice.

If lamps having no resistance in the base are operated on any of the voltages indicated in table II, the resistance value shown for a given voltage should be increased by the amount normally used in the base of the corresponding screw-base lamp as shown in table III.

Example. If, in the example given above, a nonresistance lamp were used, the external resistance value should be increased to 123,000 ohms.

Response Speed

The response speed of neon negative-glow lamps can be explained along three definite lines. First, the ignition or breakdown voltage of glow lamps varies with the duration of voltage application. This is because the discharge has a time lag, and the voltage required for breakdown increases the shorter the duration of application. It is known that the breakdown may increase 50 volts for a time application of 0.01 second and increases further for shorter time intervals.

Table I

Type Lamp	Supply Voltage	Breakdown Voltage	Minimum Maintaining Voltage	V_0	Ohms R_i	Ohms R_x
S-14-3 watt	120 a-c	53	50	43	310	2,200

Second, the light-current response begins to lose a linear relationship in the neighborhood of 15,000 cycles. For certain uses, however, the current-light response has been used at much higher equivalent frequencies.

Third, after the discharge has been started, the lamp will restart at the maintaining voltage if the current is interrupted for a period not greater than 0.02 second; the normal breakdown is not reached until approximately 0.1 second elapses.

The Influence of Surrounding Light

Practically all glow lamps that start under 90 volts direct current have electrode surfaces so sensitive that they emit electrons photoelectrically when light falls on them. This current emission aids in reducing the breakdown of the lamp. For example, a standard glow lamp measured in the dark had a d-c breakdown of 75 volts and a maintaining voltage of 60 volts; measured in a normally lighted room the breakdown was 73 volts. The same lamp when placed several inches away from a 200-watt incandescent lamp burning at normal voltage broke down at 60 volts. Further increase in illumination did not alter the breakdown, but a sensitive galvanometer placed in the lamp circuit showed current changes with changes in illumination intensity.

Figure 5. A glow lamp used to check conductivity of liquids

Figure 6. Shunt resistors may be used to regulate the sensitivity of glow lamps

Effect of Temperature

Due to the sensitivity of the surface of the electrodes they will emit electrons even at normal room temperatures. When ambient temperatures become as high as 75 to 150 degrees centigrade the breakdown voltage is lowered to some extent. An effect of ambient temperatures of the range of 180 to 200 degrees centigrade is to evolve gases from the glass wall that poison the electrode surfaces. No appreciable effect of temperature can be observed in the range of 0 to 50 degrees centigrade.

The Nature of the Radiation From Glow Lamps

Neon negative-glow lamps radiate mainly in the red and yellow region of the spectrum; there is some radiation from the infrared that is invisible to the eye; a little radiation is spread from the yellow region into the violet. There is very little invisible radiation on the violet side between the violet and the transmission limit of the glass bulbs. The glass bulbs absorb whatever small amount of therapeutic ultraviolet radiation may be generated in the discharge.

Argon glow lamps, which consist of a mixture of gases, radiate mainly in the blue, violet, and near ultraviolet region. The negative glow appears blue-violet. The fact that there is strong radiation in the near ultraviolet region can be demonstrated by the fluorescent effects produced on uranium glass and many phosphorescent and fluorescent substances. The near ultraviolet radiation can be determined by other means too—for example, with a photo-cell, or by photographic means. Here again, the glass container absorbs any ultraviolet of therapeutic value, if it is generated. A recent trial of argon lamps in high-speed photographic printing machines has shown an enormous advantage over all other light sources.

Standard Lamps

A group of glow lamps is now available which covers a wide range of uses and

applications, as shown in figure 2 and the listing of pertinent data in table III.

Applications and Uses

The unique characteristics of the glow lamp lend themselves to many applications and uses which would be quite impossible with devices not possessing these characteristics. Its ability to produce light at low energy levels suggests its use as a signal or pilot in circuits where little current is available or where low current drain is desirable, as in radio circuits, "B"-battery-operated devices, and high-resistance circuits. It may be used in capacitively or inductively coupled circuits where little current may be drawn.

As a Test Lamp

The glow lamp makes an ideal all-around test lamp. It will indicate

1. Circuit alive—circuit continuity
2. By brilliancy, whether 110 or 220 volts
3. By flicker, if 25 cycle
4. Polarity (only negative glows on direct current)
5. Grounded neutral wire. Holding one lead in hand and touching separately each of three legs of a three-wire system with the other lead, the two live lines will cause a glow. Lamp will not light on grounded neutral.

High sensitivity suits the lamp to many high-resistance tests, such as checking leakage in capacitors (figure 3); leakage between tube elements; leaks in insulating material (figure 4); conductivity of liquids (figure 5) and many similar uses.

When the lamp proves to be too sensitive, showing up conditions which may not be particularly serious, the lamp sensitivity may be regulated by shunting a high resistance across it (figure 6).

As a Signal or Pilot Lamp

In many cases the lamp may be permanently connected in a production line or on a machine to indicate the occurrence of certain conditions. It might be used as an indicator of any of the conditions mentioned under the heading "As a Test Lamp".

As a low-current, dependable, long-life pilot lamp, the glow lamp is outstanding and has already been used extensively on all kinds of electrically heated or operated devices, as well as for exit lights, fire-station markers, and location signals for valves, switches, or other emergency control units.

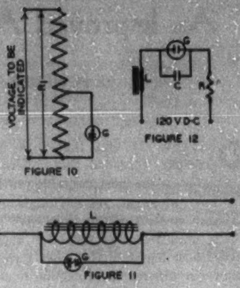
Some further pilot lamp applications are shown in the following sketches:

Figure 7. When fuse blows, the respective glow lamp will light.

Figure 8. As a control for polyphase lines. When one phase is overloaded, the respective glow lamp will dim or go out, depending on voltage drop.

Figure 9. To indicate that high-voltage lines are carrying current. The small capacity current will cause lamp to glow.

Figure 10. As a visual voltmeter. When desired voltage develops across R_1 the voltage across the lamp rises to the breakdown value causing it to light.



Figures 10–12

Many other adaptations may be made of the critical breakdown voltage of the glow lamp by connecting it across resistors, chokes, or current transformers so chosen that the normal drop across the lamp is below breakdown. Then, any condition which causes the voltage to reach the breakdown value will be indicated by a glow in the lamp. (Figure 11.)

As a Low-Frequency Generator

If a glow lamp is shunted across a capacitance and connected through a resistance to a d-c supply, the capacitor will charge up to the breakdown voltage and discharge through the lamp. By proper selection of the circuit constants, the lamp may be made to flash or in fact to oscillate at frequencies well up into the audio range. (Figure 12.) The addition of choke L_1 insures uniformity of oscillation and may vary from 1 to 30 henrys.

* Lamps supplied without resistance only when equipped with double-contact bayonet base.

† Lamps listed in clear finish are available with sprayed red or yellow finish, except in the one-fourth-watt sizes.

‡ On direct current, only one electrode (negative) glows, but gives same candlepower as do both electrodes on alternating current.

** Supplied in one-watt size for 210–240-volt a-c or d-c service, medium screw base only.

♯ Available in skirted candelabra screw base.

Note: Normal light output is obtained at voltage range shown. Lamps will operate at reduced light output down to starting voltage shown.

An Improved A-C Pilot-Wire Relay

J. H. NEHER
MEMBER AIEE

A. J. McCONNELL
ASSOCIATE AIEE

DESPITE the fact that it is quite generally conceded that differential protection is the most desirable principle for line protection, yet few applications of relay systems of this type have been made until recently except for lines of very short length. The older forms of pilot-wire differential protection required three or four wires of low resistance; and even then, the systems were characterized by lack of sensitivity, and by high burden on the current transformers.

Because of the general availability of reliable communication facilities between power stations, d-c pilot-wire systems,[1] utilizing a single pair of telephone-type pilot wires, have been developed. These systems operate on the "directional comparison" principle, hence require a potential supply for the relays, and may be influenced by out-of-step conditions. The relays ordinarily used are not easily insulated to protect against induced voltages. While the requirement for a potential supply, the tendency to operate on out-of-step conditions, and the matter of relay insulation are not always influencing factors in the choice of a relay system, there are, of course, advantages in the use of a system which would not be so limited.

A differential system which uses a single telephone pair as a pilot circuit is definitely limited by the energy which can be transmitted over the pilot wires. This energy limit is far below that required by the older forms of differential protection; and some means must be found for making the single relay system operative on all types of faults. Such a relay system has been developed[2] in which these difficulties have been solved by the use of supersensitive relay elements and networks.

This paper describes a similar relay system in which one standard relay element is used at each terminal. It is operative over a single telephone pair and gives full protection for any type of fault without the need for a potential supply. In addition, there is adequate insulation between the relay element and the pilot wires. The relay is of the current product type, in which the energy required to operate the element is provided largely by the polarizing current; thus permitting the use of a relatively low energy level in the pilot-wire circuit.

In many respects this system is similar to the "Translay" system[3,4] used successfully in Europe for many years. Of its several improvements, an outstanding one is the use of the modern high-speed induction-cylinder relay element.

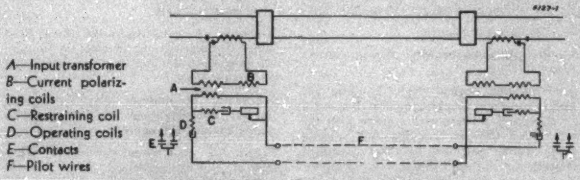

Figure 1. Single-phase schematic diagram of relay circuits

Basic Principles of the Pilot-Wire System

Fundamentally, the system is of the opposed-voltage type in which substantially no current flows in the pilot wires under normal, or through fault conditions.

Figure 1 shows the fundamental circuits on a single-phase basis. At each end of the line, the current transformer energizes the following two elements:

1. The polarizing coils of a wattmetric type of relay element.
2. The primary of the "input transformer" which is a reactor with a secondary winding.

Current flow in the primary of the input transformer causes a voltage to be induced in the secondary. This voltage is applied to a shunt-connected restraining circuit, and to the operating circuit which is in series with one of the pilot wires.

The current which flows in the restraining coil of the relay reacts with the polarizing coil current to produce a torque in the contact-opening direction.

The current which flows in the operating-coil circuit is dependent upon the voltages of the input transformers at both ends of the line. Under normal or through fault conditions, these voltages oppose each other, and practically no

Discussion

Discussion will be found in the 1941 annual TRANSACTIONS volume and in the June 1941 SUPPLEMENT to ELECTRICAL ENGINEERING—TRANSACTIONS SECTION.

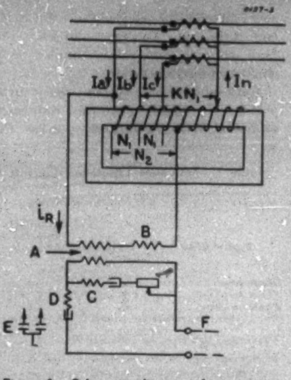

Figure 2. Schematic diagram of one termina showing connections of autotransformer

A, B, etc., same as figure 1

current flows in the pilot wires. With an internal fault, the voltages are additive; and the resultant current flowing in the operating circuit reacts with the polarizing current, and produces a torque in the contact-closing direction of sufficient magnitude to overcome the restraining torque. On an internal fault, the pilot-wire current is proportional to the sum of the fault currents entering each end.

The wattmetric type of element used is of the multipole induction-cylinder construction which has previously been described before the AIEE.[5] Three of the potential coils are used in the operating circuit, and the fourth furnishes the restraint. The four current polarizing coils are connected in series.

Purpose of Capacitors in Operating and Restraining Circuits

Since the torque of a wattmetric type of relay is proportional to the product of two currents and the sine of the angle between them, maximum torque occurs when the two currents are displaced by 90 degrees. The secondary voltage of the input transformer is displaced by 90 degrees from the current in the primary. Thus, for maximum torque, the currents flowing in the operating circuits must be in phase with the voltages producing them. For this purpose, capacitors are used in both the restraining and operating circuits; both circuits being resonant at rated frequency.

Besides producing a high-efficiency relay, other beneficial effects are obtained from the resonant operating circuit. The current which flows in the operating circuit, because of the electrostatic capacity of the pilot wires, is highly leading; and therefore, is almost in phase with the polarizing current. In consequence, substantially no operating torque is produced by pilot-wire capacity current. Hence, greater sensitivity is possible without interference by capacity current. The resonant circuit suppresses harmonic currents in the pilot wires; especially the higher noise-producing harmonics. Also, the effect of currents caused by switching transients is greatly reduced, since such currents usually contain a variety of harmonics. Thus, the pilot circuit is both free from outside interference, and at the same time, does not itself produce troublesome telephone interference. Since differences in current transformers usually involve a phase-angle shift as well as a change in the ratio, the voltages applied to the pilot wires may be out-of-phase during an external fault. However, the circulating current which flows through the pilot wires because of phase shift is at an angle unfavorable to the development of full relay torque.

Purpose of the Wattmetric Type of Relay Element

Since the operating torque of the relay element depends upon both the polarizing and the pilot-wire currents, most of the driving energy of the relay can be concentrated in the polarizing coils, thus making it possible to obtain a satisfactory torque level with a small amount of power transmitted over the pilot wires. Thus, special pilot wires of extremely low resistance are not required.

Open and Short-Circuited Pilot Wires

This pilot-wire system is subject to the disadvantage common to all pilot-wire systems, namely, incorrect operation when the pilot wires are either open-circuited or short-circuited. An open-circuited pilot wire will prevent tripping on an internal fault; whereas short-circuited pilot wires will cause tripping on external faults.

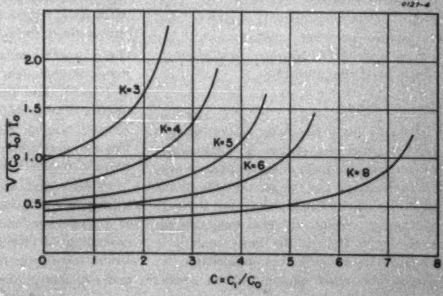
Figure 3. Vector diagrams of relay currents

Figure 4. Pickup current on phase C-ground fault (zero pilot-wire resistance)

Method of Obtaining Polyphase Protection

Thus far, the pilot-wire relay system has been considered on a single-phase basis only, in order to show that it operates in response to circulating current



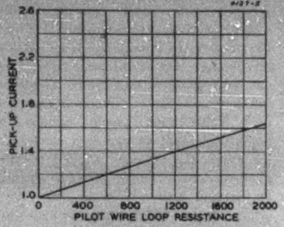


Figure 5. Effect of pilot-wire resistance on pickup current

Pickup current plotted as multiple of pickup current with zero pilot-wire resistance

in the pilot wires reacting with the polarizing current. In order that a single pair of relays can furnish protection for all phase and ground faults over a single pair of pilot wires, it is necessary to provide some means of impressing on the relay system a single electrical quantity for any type of fault.

It is often true that the simplest device also provides the most satisfactory performance. In this instance, a simple tapped autotransformer is the means of providing the single electrical quantity.

Figure 2 shows the connections to and from the autotransformer. The autotransformer is interposed between the current transformers and the remaining relay circuits. Considering the two left-hand sections of the autotransformer, it is obvious that its output, during phase faults, is proportional to $(I_a - I_c)$. During ground faults the residual current flows through the right-hand section, producing a component of output current which is proportional to I_n times factor K. K is a constant relating the turns in the phase and ground windings, and is adjustable by means of taps. The total output current of the autotransformer is therefore proportional to $I_a - I_c + KI_n$ (equation 3, appendix I).

Figure 3 shows vectorially the relations between positive, negative, and zero-phase-sequence currents, and the output current of the autotransformer on faults involving ground.

Blind Spots

When a pilot-wire relay system utilizes any network to obtain a single-phase output current from a three-phase source, there is always the danger that the relays at both ends of the line may fail to operate under certain internal fault conditions, even though the fault current is apparently of sufficient magnitude to exceed the relay pickup. Such conditions may be termed "blind spots". Any such relay system must be carefully analyzed to determine its limitations in this respect. In general, "blind spots" are possible only on faults involving ground.

With the relay system described above, one of the following conditions is necessary for a "blind spot" to occur:

1. A low autotransformer output current at *each* end of the line.
2. A low pilot-wire current.
3. An unfavorable phase angle between the pilot-wire and polarizing currents at *each* end of the line.

It is possible (although usually avoidable by properly selecting constant K) to have a low autotransformer output at one end of the line. However, with a solidly grounded neutral system, it is not possible to have a low autotransformer output at each end of the line simultaneously; nor are any of the other conditions possible.

In unusual instances, it may not be possible to avoid a low polarizing current at one end of the line. The relay at the other end of the line will operate, however, and after the circuit breaker at that end opens, the relay at the first end will operate sequentially, provided, of course, that there is sufficient current for operation on single-end-feed.

A low autotransformer output current at one end is caused by unequal distribution of positive and zero-phase-sequence currents. For example, it can be seen (figure 2) that with a C phase-ground fault, the current in phase C can divide in such a manner that I_n will flow in one direction, and the remainder of the current in phase C will flow in the opposite direction. (See also equation 29, appendix II.) The C phase-ground fault is the limiting condition in this respect (appendix II), and figure 4 provides a ready means for selecting the constant K in order to insure adequate torque for simultaneous relay operation with a C phase-ground fault. These curves show the relay pickup in terms of the geometric mean $(\sqrt{(c_0I_0)(I_0)})$ of the zero-phase-sequence current fed from one end (c_0I_0), and the total zero-phase-sequence current (I_0), for various values of K and $c = c_1/c_0$, where c_1 and c_0 are positive and zero-phase-sequence distribution factors, respectively.

In those cases in which it is apparently impossible to avoid sequential tripping, it is sometimes possible to eliminate the cascading of circuit breaker times by a simple arrangement whereby the operation of either pilot-wire relay immediately short-circuits the pilot-wire circuit at its end of the line. To the second relay, the fault then appears to be similar to a single-end-feed condition.

With an overhead system, the neutral points of which are all resistance grounded, it is theoretically possible for the relays at one or both ends to develop insufficient or negative torque on a C phase-A phase-ground fault. This can be noted from equation 35 given in appendix II. The large number of variables in this equation prevents a simple treatment such as has been given above in the case of a single-phase-to-ground fault. A study of this equation indicates, in general, that if simultaneous operation is obtained at both ends on all phase-to-phase faults, sufficient torque will be available to operate both relays under any practical case of resistance grounding, although sometimes the operation may be sequential.

Table I. Minimum Operating Currents

Type of Fault	Phases	CT Secondary Pick-Up Amperes
Three-phase	A-B-C	4
Phase-to-phase	A-B and B-C	7
Phase-to-phase	A-C	3.5
Single-phase-to-ground	C-ground**	1.0 to 3.5*

* Five taps to adjust for constant K.

** Pick-ups slightly less on phases A and B.

G—Supply transformer

Characteristics of the Relay System

Minimum Operating Current

Based on single-end-feed, table I gives the minimum operating currents on various types of faults. These values are based on zero pilot-wire resistance. Since the operating coil current decreases as the pilot-wire resistance increases, the pickup current will increase. The effect of pilot-wire resistance upon pickup is shown in figure 5.

Operating-Restraining Characteristics

If saturation of the mixing transformers could be neglected, the slope of the operating-restraining curve on a through fault would be approximately 50 per cent; that is, differential current in per cent of the smaller of the restraining currents. However, saturation of the mixing transformer causes the slope to increase rapidly at the higher currents as shown in figure 6.

This characteristic permits the use of unmatched current transformers or burdens. Since the operating current varies with the resistance of the pilot wire, means are provided to adjust the restraining current so that substantially the same curve applies regardless of the pilot-wire resistance.

Current Transformer Burden

The three-phase burden is less than one volt-ampere per phase at five amperes. The single-phase-to-ground burden varies between 12 and 57 volt-amperes at five amperes, depending upon the ground tap (constant *K*) used.

Operating Time

The time-current curve is shown in figure 7. This curve is based upon single-end-feed. Operating times are slightly less when additional operating current is received over the pilot wires from the other end of the line.

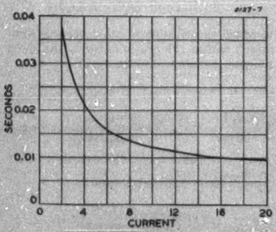

Figure 7. Operating time

Current plotted as multiple of minimum pickup with single-end-feed

Pilot-Wire Circuit

The reliability of any pilot-wire protective scheme is dependent upon continuity of the pilot channel. Interruptions may occur from electrical and mechanical causes which include the following:

1. Induction from power lines.
2. Difference in station ground potentials.
3. Lightning.
4. Contact with foreign objects.
5. Unauthorized tampering with pilot circuits.

Experience has indicated that the use of lead-sheath cable of sufficient insulation and mechanical strength practically eliminates trouble from the first four hazards. Elimination of interruptions caused by trouble-shooting, etc., can be accomplished by treating the pilot-wire circuit as any high-voltage power circuit, thus requiring clearance orders from the dispatcher. If the circuits are leased, co-ordination is necessary between the lessee and lessor.

Insulation stress caused by induction can be reduced by the use of different routes for the power lines and pilot cable.

The difference between station ground potentials is largely concentrated near the power station. If this potential difference is large, it may be economical to use two different levels of cable insulation strength, using the higher level close to the stations. In such instances, neutralizing transformers[8] can also be considered.

Whether the voltage is derived from induction, or rise in station ground potential, each relay is protected by means of an insulating transformer tested at over 10,000 volts between the pilot-wire winding and ground, and between the pilot-wire winding and the relay winding.

In addition to insulation problems, induction may be the cause of further difficulty, namely, incorrect operation because of a voltage difference between the pilot wires. If the pilot-wire circuit is the preferred twisted pair, this voltage difference does not have to be considered. However, if the pilot wire circuit is other than a twisted pair, it should be determined that the voltage between wires is less than five volts under maximum fault conditions.

Pilot-Wire Supervision

Since the pilot wires are such an important part of the relay system, manual pilot-wire checking equipment is furnished with each relay. The equipment consists of a voltmeter and a switch (*A* and *B* in figure 8). When the switch is operated, the voltage transmitted from the relay at the opposite end of the pilot wires is read. A positive reading indicates a sound operating circuit including both insulating transformers and the relay at the other end of the line. A zero voltage reading indicates a short circuit or open circuit, provided, of course, there is sufficient load current to produce a voltmeter deflection.

Voltmeter readings taken at the same time as the usual periodic readings should provide an ample check of the pilot circuit. However, some operators may desire a continuous automatic check of the pilot wires. The automatic supervisory equipment is shown schematically in figure 8. A small direct current is circulated continuously over the pilot wires. Sensitive polarized relays at each end indicate a short-circuited or an open-circuited pilot channel, and close alarm circuits at each station. The source of direct current is a rectifier supplied from a small transformer. Each relay is tested at 10,000 volts between the pilot-wire circuit and both low-voltage circuits, and between the pilot-wire circuit and the relay case.

Conclusion

In conclusion, it is felt that the relay system described, offering protection against all types of faults, and consisting of a relatively simple arrangement of standard components, constitutes a definite step toward meeting the requirements of the ideal relay scheme.[7]

Appendix I

Operation of the Mixing Autotransformer

From figure 2 it is evident that the ampere-turn balance in the mixing autotransformer will always be as follows:

$$N_2 i_R = N_1[I_a(1+K)+I_bK+I_c(K-1)] \quad (1)$$

Since

$$I_n = I_a+I_b+I_c \quad (2)$$

$$I_R = I_a-I_c+KI_n \quad (3)$$

where

$$I_R = \frac{N_2}{N_1}i_R \quad (4)$$

is the current fed to the relay element, referred to the input side of the mixing autotransformer.

Equation 3 may be resolved into its phase-sequence components as follows:

$$I_a = I_{a1}+I_{a2}+I_{a0} \quad (5)$$

$$\begin{aligned} I_c &= I_{c1}+I_{c2}+I_{c0} \\ &= I_{a1}\underline{/120^\circ}+I_{a2}\underline{/-120^\circ}+I_{a0} \end{aligned} \quad (6)$$

$$I_n = 3I_{a0} \quad (7)$$

$$I_R = \sqrt{3}I_{a1}\underline{/-30^\circ}+\sqrt{3}I_{a2}\underline{/30^\circ}+3KI_{a0} \quad (8)$$

The derivation of the currents fed to the relay elements under the various fault conditions will be made on the assumption that the positive and negative-phase-sequence networks are identical, and that the positive and zero-phase-sequence networks have the same phase angle, except as noted hereafter.

The resultant relay currents for all types of faults will be expressed in terms of three fundamental currents

$$I_P = \frac{\sqrt{3}E}{2Z_1} \quad (9)$$

which is the total phase-to-phase fault current

$$I_N = \frac{3E}{2Z_1+Z_0} \quad (10)$$

which is the total ground current for a single-phase-to-ground fault, or

$$I_{N'} = \frac{3E}{Z_1+2Z_0} \quad (11)$$

which is the corresponding total ground current on a two-phase-to-ground fault. In equations 9, 10, and 11, the voltage, currents, and impedances can be considered to be scalar quantities, since it has been assumed that Z_1 and Z_0 have the same phase angle.

The following expressions for the resultant relay currents on faults not involving ground are self-evident from equation 3. (C_1 and C_0 are the current distribution factors for the positive and zero-phase-sequence networks, respectively.)

(*a*). Three-phase and *C* phase-*A* phase faults

$$I_R+2c_1I_P \quad (12)$$

(*b*). *A* phase-*B* phase and *B* phase-*C* phase faults

$$I_R = c_1I_P \quad (13)$$

The derivation of the relay current on faults involving ground can best be made from equation 8 and the vector diagram shown in figure 3.

(*c*). *A* phase-ground fault

$$I_R = (Kc_0+c_1)I_N \quad (14)$$

(*d*). *B* phase-ground fault

$$I_R = Kc_0I_N \quad (15)$$

(*e*). *C* phase-ground fault

$$I_R = (Kc_0-c_1)I_N \quad (16)$$

In the case of two-phase-to-ground faults the following relationships have been employed which are justifiable in view of the assumption that $Z_2 = Z_1$. Here again, I_1 and I_2 are scalar quantities, and are the magnitudes of I_{a1} and I_{a2}, respectively.

$$I_1+I_2 = \frac{(Z_1+Z_0)E}{Z_1(Z_1+2Z_0)}+\frac{Z_0E}{Z_1(Z_1+2Z_0)} = \frac{E}{Z_1} \quad (17)$$

$$I_1-I_2 = \frac{E}{Z_1+2Z_0} \quad (18)$$

(*f*). *A* phase-*B* phase-ground fault

$$I_R = c_1I_P-j(Kc_0+c_1/2)I_N' \quad (19)$$

(*g*). *B* phase-*C* phase-ground fault

$$I_R = c_1I_P-j(Kc_0-c_1/2)I_{N'} \quad (20)$$

(*h*). *C* phase-*A* phase-ground fault

$$I_R = 2c_1I_P+jKc_0I_{N'} \quad (21)$$

Appendix II

Relay Torque Equations

From figure 1 and the discussion given in the text it is apparent that the torque developed by the relay in terms of the pick-up torque t can be expressed as:

$$T = \frac{I_R}{t}\left(\frac{N_1}{N_2}\right)^2 k\left[\frac{I_R-I_{R'}\cos\theta}{2R_o+R_p}-\frac{I_R}{3R_r}\right] \quad (22)$$

where

I_R = the current fed to the relay element at the end under consideration

$I_{R'}$ = the current fed to the relay element at the other end

θ = the phase angle between I_R' and I_R

k = transreactance of the pilot-wire input transformers

R_o = resistance of relay operating circuit

R_r = resistance of relay restraint circuit

R_p = resistance of pilot-wire loop

With the restraint circuit properly adjusted for 50 per cent slope, equation 22 becomes, with the proper values substituted:

$$T = \frac{I_R}{32.5F}[I_R-I_{R'}\cos\theta-I_R/3] \quad (23)$$

where the effect of the pilot-wire resistance is given by

$$F = 1+\frac{R_p}{1,140} \quad (24)$$

By the use of equation 9 through 16, and 19 through 21, equation 23 may be solved to give the torque developed on internal faults ($\theta = 180$ degrees) for the various phase and ground combinations. The expressions for pilot-wire currents $(I_R+I_{R'})$ are similar to the corresponding expressions for I_R with c_1 and c_0 made unity where they occur.

When I_R and $(I_R+I_{R'})$ have reactive components no torque can result from the cross-product terms.

(*a*). Three-phase and *C* phase-*A* phase faults

$$T = 4\frac{I_P^2}{32.5F}c_1(1-c_1/3) \quad (25)$$

(*b*). *A* phase-*B* phase and *B* phase-*C* phase faults

$$T = \frac{I_P^2}{32.5F}c_1(1-c_1/3) \quad (26)$$

(*c*). *A* phase-ground fault

$$T = \frac{I_N^2}{32.5F}(Kc_0+c_1)[K+1-(1/3)(Kc_0+c_1)] \quad (27)$$

(*d*). *B* phase-ground fault

$$T = \frac{I_N^2}{32.5F}Kc_0(K-Kc_0/3) \quad (28)$$

(*e*). *C* phase-ground fault

$$T = \frac{I_N^2}{32.5F}(Kc_0-c_1)[K-1-(1/3)(Kc_0-c_1)] \quad (29)$$

It is apparent here that reduced or negative torque can be obtained, depending upon the relative values of Kc_0 and c_1. Equation 29 can be rewritten in the following form:

$$T = \frac{I_N^2}{32.5F}c_0(1-c_0/3)\left[K\left(K-\frac{3-c_1}{3-c_0}\right)-\frac{c_1}{c_0}\left(K-\frac{3-c_1}{3-r_0}\right)\right] \quad (30)$$

in which the solution of the expression contained within the brackets forms the basis of figure 4 discussed in the text.

(*f*). *A* phase-*B* phase-ground fault

$$T = \frac{I_P^2}{32.5F}c_1(1-c_1/3)+\frac{1}{4}\frac{I_{N'}^2}{32.5F}(2Kc_0+c_1)\times [2K+1-(1/3)(2Kc_0+c_1)] \quad (31)$$

(*g*). *B* phase-*C* phase-ground fault

$$T = \frac{I_P^2}{32.5F}c_1(1-c_1/3)+\frac{1}{4}\frac{I_{N'}^2}{32.5F}(2Kc_0-c_1)\times [2K-1-(1/3)(2Kc_0-c_1)] \quad (32)$$

Here again, it is possible that a negative torque from the second half of equation 32 will offset the positive torque of the first part of the equation. It is apparent, however, that the relationships between Kc_0 and c_1 required to render equation 29 positive will also make the second part of equation 32 positive.

(*h*). *C* phase-*A* phase-ground fault

$$T = 4\frac{I_P^2}{32.5F}c_1(1-c_1/3) + \frac{I_{N'}^2}{32.5F}Kc_0(K-Kc_0/3) \qquad (33)$$

In the case of a two-phase-to-ground fault with the system grounded through a resistance, the previous assumption that Z_1 and Z_0 have the same phase angles is no longer valid. The introduction of an additional resistance component in Z_0 will advance the components containing $I_{N'}$ in phase position. This will increase the values of torque developed from equations 31 and 32 but may decrease it in the case of equation 33.

Although equation 21 was derived on the basis that I_P and $I_{N'}$ were scalar quantities, it can be shown that the equation is also valid when I_P and $I_{N'}$ are vectors. If the resistive and reactive components of Z_1 and Z_0 are R_1, X_1 and R_0, X_0 respectively, then the angle of advance of $I_{N'}$ is given by the following expression

$$\phi = \tan^{-1}\frac{X_1}{R_1} - \tan^{-1}\frac{X_1+2X_0}{R_1+2R_0} \qquad (34)$$

Equation 21 in appendix I becomes

$$I_R = 2c_1I_P - I_{N'}Kc_0 \sin\phi + jI_{N'}Kc_0\cos\phi \qquad (21a)$$

and equation 33 becomes

$$T = 4\frac{I_P^2}{32.5F}c_1(1-c_1/3) - \frac{2KI_PI_{N'}}{32.5F} \times [c_1(1-c_0/3) + c_0(1-c_1/3)]\sin\phi + \frac{I_{N'}^2}{32.5F}Kc_0(K-Kc_0/3) \qquad (35)$$

in which a negative torque term now appears.

Vario-Losser Circuits

W. R. BENNETT

NONMEMBER AIEE

Synopsis: Methods are given for the design of circuits using "varistor" elements to secure specified variations of loss as a function of input signal. The types of circuits include compressors and expandors using shunt, series, and lattice networks. Formulas for steady-state transmission and distortion in terms of varistor characteristics are developed.

THE functions performed in the telephone plant by various automatic gain-control devices such as vogads and compandors have been described in a number of published articles. These devices have the common property that the gain or loss of a portion of the circuit is made to vary in accordance with changes in the transmitted signal. The term vario-losser is used to designate that part of the system in which the change in loss or gain actually occurs. Vario-lossers operating by virtue of the change in gain or plate impedance of vacuum tubes as a function of varying grid bias have been described elsewhere.[1,2,3] In this paper there are discussed the design considerations for certain simple vario-losser circuits which make use of "varistors," that is, nonlinear elements such as copper oxide and silicon carbide in which the resistance is a function of current or voltage, to furnish the desired variation in loss. These circuits have the advantage of low initial cost, stable properties, long life, and simple maintenance requirements.

It should be kept in mind that in general it is not the instantaneous value of the signal wave which controls the loss or gain of the vario-losser, but some more slowly varying quantity such as the "volume" or "envelope." Since "volume"[*] controlled circuits require control arrangements of a very high degree of complexity, which do not necessarily affect the vario-losser design, we shall limit our discussion to considerations of "envelope" control. The same considerations would of course enter into "volume" control design.[4]

In "envelope" control, a control current or voltage is commonly derived by rectifying the signal and sending the rectified output through a network (for example, a shunt capacitor and series resistance) which discriminates against the higher frequencies. For our purposes, we shall refer to a current or voltage obtained in this way as representing the envelope of the signal and designate its amplitude by capital letters *I* or *V*. The instantaneous values will be designated by lower case letters *i* and *v*. Furthermore we shall assume that the envelope varies at such a slow rate that what is under consideration is essentially the steady state.

The operating point of and hence the loss produced by the varistors is determined by the amount of current or voltage bias furnished by the control current, which is in turn fixed by the envelope. The range of variations of the instantaneous signal about the operating point is limited to a region in which the varistors are substantially linear. Under these conditions, the wave form of the signal is preserved, and we may say that the ratio of instantaneous signal output to instantaneous signal input is the same as that of envelope output to envelope input. As general equations therefore, we write

$$v_2/v_1 = V_2/V_1 = A \qquad (1)$$

where the subscripts 1 and 2 refer to input and output voltages, respectively and *A* is a voltage transfer ratio determined by the envelope. If the value of *A* is determined by V_1, the input voltage, the device is said to be *forward acting;* if *A* is determined by V_2, the device is said to be *backward acting*. The usual law of operation desired is that in which the output envelope varies as some power of the input envelope, that is:

$$V_2 = kV_1^n \qquad (2)$$

where *k* and *n* are constants. If *n* is less than unity, the device is called a *compressor*, since a given range of variation of input envelope produces a smaller range of variation in output envelope. When *n* is greater than unity, the device is called an *expandor*, since the range of variation of envelope is increased by the device.

Paper 40-136, recommended by the AIEE committee on communication, and presented at the AIEE Pacific Coast convention, Los Angeles, Calif., August 27–30, 1940. Manuscript submitted November 24, 1939; made available for preprinting July 18, 1940.

W. R. BENNETT and S. DOBA are with Bell Telephone Laboratories, New York, N. Y.

[1] For all numbered references, see list at end of paper.

[*] The term "volume" is used here to designate that quantity measured by the volume indicator.

The value of n is called the *control ratio.*[5] Obviously if n is equal to unity the device has a fixed loss or gain and does not operate as a vario-losser.

From (1) and (2),

$$A = kV_1^{n-1} \tag{3}$$

and

$$A = k^{1/n}V_2^{1-1/n} \tag{4}$$

Equation 3 may be regarded as the fundamental equation for forward acting vario-lossers, and 4 as the corresponding equation for backward acting vario-lossers. In applications to the design of specific circuits, however, it is more convenient to have the constant k appearing above expressed in terms of the loss or gain at some particular value of load, for example, the maximum operating value. We shall represent the reference condition by a zero subscript, that is, $A = A_0$, $V_1 = V_{10}$, $V_2 = V_{20}$, etc. Equations 3 and 4 then become

$$A = A_0(V_1/V_{10})^{n-1} \tag{3a}$$

$$A = A_0(V_2/V_{20})^{1-1/n} \tag{4a}$$

If the input and output impedances terminating the vario-losser are equal, the loss in decibels is 20 $\log_{10}(1/A_0)$ when the input voltage is V_{10} and the output voltage is V_{20}.

Some discussion should be inserted here concerning the actual current-voltage characteristics available in typical varistor elements. In order that a vario-losser may operate satisfactorily over the range of inputs desired, varistor elements must be provided whose resistances can be controlled in the desired manner over a similar range. Anticipating some of the results derived in the next section, dealing with specific circuit arrangements, we point out that a particularly suitable type of curve for varistors from the theoretical standpoint is that in which the current is an exponential function of the voltage over a considerable range. That such behavior can actually be realized to within small error except for low currents is indicated by the measured curve, figure 1, for copper oxide. Semilogarithmic co-ordinate paper is used, which yields a straight-line graph when the function plotted is exponential. Circuits in which the exact form of the varistor characteristic is not critical also exist; they will be discussed under the section on marginal detector types.

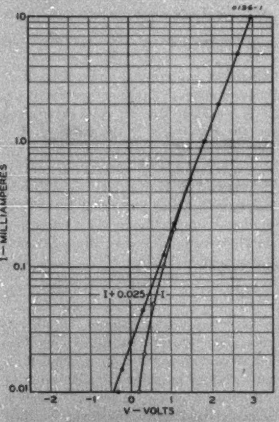

Figure 1. Current versus voltage for typical copper-oxide varistor

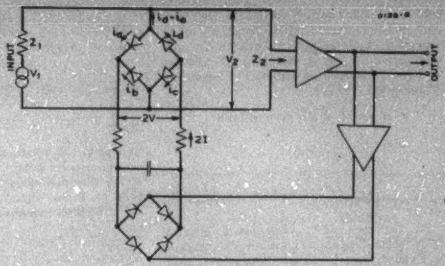

Figure 2. Shunt-type backward-acting vario-losser

It should be noted also that in supplying the bias derived from the envelope for controlling the varistor resistances, minimum complexity is secured if the biasing current or voltage is made linearly proportional to the envelope amplitude. It will appear from the discussion to follow, that the combination of a linear current relation with the exponential varistor characteristic is particularly favorable to compression or expansion in the ratio of 2:1. No such simple results are obtained with voltage-controlled devices. We shall therefore confine our treatment to current-controlled devices with the exception of one type of voltage-controlled vario-losser which has the interesting property that a continuous variation of the compression or expansion ratio may be secured.

The general problem is then that of determining the varistor characteristic to obtain the required exponent n with a suitable—generally a linear—rectifier.

Types of Vario-Losser Circuits

From the standpoint of circuit configuration, vario-lossers may be classified as either of the two-terminal or four-terminal type, depending on whether the varistor combination is inserted merely as an impedance element or as a general transmission network. The two-terminal class may be further subdivided into the series and shunt types. The four-terminal class will be represented in this discussion by the lattice type, which is sufficiently general for illustrative purposes.

Two-Terminal Networks

SHUNT TYPE

A shunt-type vario-losser may be constructed by shunting the signal path with nonlinear elements having low resistance compared to that of the remainder of the circuit. A typical circuit of the backward-acting type is shown in figure 2. A portion of the output voltage is amplified and rectified, the rectified current is transmitted through a capacitance-resistance network and then introduced into a varistor bridge. The pair of terminals of the bridge which are conjugate to the bias input are connected directly across the signal input circuit. If r represents the a-c resistance of the varistor bridge shunted across the signal circuit and Z_1, Z_2 the input and output signal circuit impedances, respectively

$$A = \frac{V_2}{V_1} = \frac{rZ_2}{Z_1Z_2 + r(Z_1+Z_2)} \tag{5}$$

If r is small compared with $Z_1Z_2/(Z_1+Z_2)$, the impedance of Z_1 and Z_2 in parallel, we have approximately

$$A = r/Z_1 \tag{6}$$

The resistance r varies with the bias current which is in turn proportional to V_2. Let I represent the bias current through and V the bias voltage across one varistor element. For simplicity the elements are assumed to be identical; it follows that r is also the a-c resistance of one element. Then

$$r = dV/dI \tag{7}$$

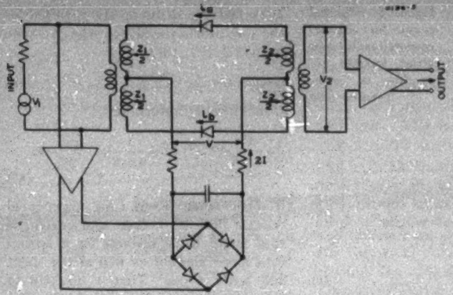

Figure 3. Series-type forward-acting vario-losser

If the impedance of the varistor bridge is low compared with the internal impedance of the rectifier-filter circuit, I is proportional to V_2 and may be written as

$$I = I_0 V_2 / V_{20} \tag{8}$$

Substituting the appropriate expression for A from (4a) in (6) and (7)

$$r = Z_1 A_0 (V_2/V_{20})^{1-1/n} = dV/dI \tag{9}$$

whence, substituting (8),

$$dV = r_0 (I/I_0)^{1-1/n} dI \tag{10}$$

Integrating, we thus obtain the general current-voltage relation for the typical varistor element, necessary to make the device satisfy (2),

$$V = \frac{r_0 I_0}{2-1/n}(I/I_0)^{2-1/n} + C$$
$$= V_0 (I/I_0)^{2-1/n} + C \tag{11}$$

The value of the integration constant C must be zero if zero bias is to be included in the operating range, since current and voltage vanish simultaneously. The particular case $n = {}^1/_2$, gives the simple solution of (10),

$$I = I_0 e^{(V-V_0)/r_0 I_0} \tag{12}$$

An exponential current-voltage relation is thus appropriate for a shunt-type backward-acting 2:1 compressor. Since (12) gives a nonzero value of current when the voltage is zero, it cannot be satisfied exactly by physical materials, but it can be made to hold with sufficient accuracy for all except small values of V.

Similarly, for a shunt-type forward-acting device, we substitute, $I = I_0 V_1 / V_{10}$ and make use of (3a). We then find

$$V = \frac{r_0 I_0}{n}(I/I_0)^n + C = V_0 (I/I_0)^n + C \tag{13}$$

as the ideal current-voltage curve, and as before the value of C is zero for physical elements. This equation indicates that a material in which the current varies as the mth power of the voltage is suitable for a forward acting shunt type m:1 compressor.

If two shunt type backward acting vario-lossers with exponential varistors such as described above are connected in tandem with a separating pad or amplifier between and equal bias currents proportional to V_2, the output envelope of the second, are supplied to each losser, we would have for the over-all combination,

$$A = b(r/Z_1)^3 \tag{14}$$

From (12), $r = \alpha/\mathrm{I}$, α = constant, and since $I = aV_2$,

$$A = \frac{br_0^3}{Z_1^3}(V_{20}/V_2)^3 \tag{15}$$

Comparing with (4a), then

$$n = 1/3,\ A_0 = br_0^3/Z_1^3 \tag{16}$$

This gives a practical method of constructing a 3:1 compressor using exponential varistors. It is also readily demonstrated that the output of the first losser is compressed in the ratio 3:2. In a similar manner, using more units, we may obtain other ratios.

SERIES TYPE

Figure 3 shows a forward-acting vario-losser of the series type. Let the total a-c resistance inserted in the circuit by the nonlinear branches be r. We readily calculate

$$A = V_2/V_1 = \frac{Z_2}{Z_1 + Z_2 + r} \tag{17}$$

If r is large compared with $Z_1 + Z_2$.

$$A = Z_2/r \tag{18}$$

From (3a),

$$r = \frac{Z_2}{A_0}(V_1/V_{10})^{1-n} = 2dV/dI \tag{19}$$

If

$$I = I_0 V_1 / V_{10} \tag{20}$$

$$2dV = r_0 (I/I_0)^{1-n} dI \tag{21}$$

Integrating

$$V = \frac{r_0}{2(2-n)}(I/I_0)^{2-n} +$$
$$C = V_0 (I/I_0)^{2-n} + C \tag{22}$$

The particular case $n = 2$ gives the simple solution of (21),

$$I = I_0 e^{2(V-V_0)/r_0 I_0} \tag{23}$$

An exponential current-voltage relation is thus found to be also appropriate for a series type forward acting 2:1 expandor.

For a backward acting series type vario-losser, we substitute $I = I_0 V_2 / V_{20}$, make use of (4a), and find

$$V = \frac{r_0 I_0}{2}(I/I_0)^{1/n} + C = V_0 \left(\frac{I}{I_0}\right)^{1/n} + \mathrm{C} \tag{24}$$

This indicates a method of realizing an n:1 expandor from varistor elements in which the current varies as the nth power of the voltage.

Four-Terminal Networks

LATTICE TYPE

The two-terminal networks just described have the defect that the impedance of the vario-losser network must be either small or large compared with the impedance of the signal circuit; hence the

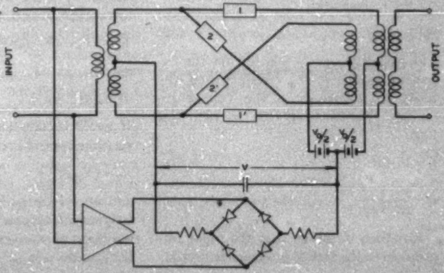

Figure 4. Lattice-type forward-acting vario-losser

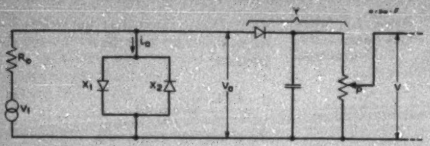

Figure 5. Control circuit for voltage-operated vario-losser giving variable expansion or compression ratio

minimum loss introduced may be excessive, and troublesome reflections caused by the mismatch may result. These difficulties may be avoided by using a lattice arrangement of varistors. In figure 4, the series varistor elements 1, 1′ have biasing voltage $(V_0+V)/2$ and a-c resistance r_1, and the shunt varistor elements 2, 2′ have biasing voltage $(V_0-V)/2$, and a-c resistance r_2. Here V_0 is a fixed direct voltage derived from a battery and V is a varying control component derived from the envelope of the signal wave. The input and output impedances of the signal circuit are assumed real and equal to R. From the equations of a lattice-type network:

$$I_1=\frac{V_1}{2}\left(\frac{1}{R+r_1}+\frac{1}{R+r_2}\right) \tag{25}$$

$$I_2=\frac{V_1}{2}\left(\frac{1}{R+r_1}-\frac{1}{R+r_2}\right) \tag{26}$$

where I_1 and I_2 are input and output currents respectively. If we let

$$r_1=Rf(V) \tag{27}$$

it follows that

$$r_2=Rf(-V) \tag{28}$$

Equations 25 and 26 then become

$$I_1=\frac{V_1}{2R}\left[\frac{1}{1+f(V)}+\frac{1}{1+f(-V)}\right] \tag{29}$$

$$I_2=\frac{V_1}{2R}\left[\frac{1}{1+f(V)}-\frac{1}{1+f(-V)}\right] \tag{30}$$

These equations permit of a useful simplification if

$$f(-V)=1/f(V) \tag{31}$$

a functional equation which is satisfied by the exponential,

$$f(V)=e^{-\alpha V} \tag{32}$$

The negative sign is selected for the exponent because in the varistors used, the resistance decreases as the voltage increases. Substituting (31) in (29) and (30),

$$I_1=V_1/2R \tag{33}$$

$$I_2=\frac{V_1}{2R}\,\frac{1-f(V)}{1+f(V)} \tag{34}$$

Equation 33 shows that the input impedance to the lattice is a constant resistance matching that of the signal circuit. When the relation (32) is substituted in (34), and the output voltage is introduced to compare with (2),

$$V_2=I_2R=\frac{V_1}{2}\tanh\frac{\alpha V}{2} \tag{35}$$

From (2), then

$$A=\frac{1}{2}\tanh\frac{\alpha V}{2} \tag{36}$$

If $\alpha V/2$ is small we have approximately,

$$A=\frac{\alpha V}{4}=A_0V/V_0 \tag{37}$$

If the device is forward-acting, we equate (3*a*) and (37), and get

$$V=V_0(V_1/V_{10})^{n-1} \tag{38}$$

We note that V is directly proportional to V_1 if $n=2$; hence a forward-acting lattice type gives a simple method of constructing a 2:1 expandor. If the device is backward acting, we equate (4*a*) and (37), giving

$$V=V_0(V_2/V_{20})^{1-1/n} \tag{39}$$

and V cannot be made directly proportional to V_2 except when n approaches infinity. The lattice type circuit is therefore best suited for a forward acting 2:1 expandor. A 2:1 compressor may however be realized by putting a 2:1 expandor in the negative feedback path of an amplifier. If an n:1 expandor is inserted in the feedback path in such a direction as to make the feedback negative, we have

$$V_g=V_1-\beta V_2^n \tag{40}$$

where V_g is the actual input voltage of the amplifier, and

$$V_2=\mu V_g=\mu V_1-\mu\beta V_2^n \tag{41}$$

or

$$V_2+\mu\beta V_2^n=\mu V_1 \tag{42}$$

If $\mu\beta V_2^n$ is made large compared with V_2, we have approximately,

$$V_2=(V_1/\beta)^{1/n} \tag{43}$$

and an n:1 compressor is secured. Similarly an n:1 expandor can be realized by inserting an n:1 compressor in the feedback path.

To find the characteristic required for the varistors in the lattice type, we write from (27), (32), (37),

$$r_1=dV/dI=Re^{-4A_0V/V_0} \tag{44}$$

from which by integration

$$I=\frac{V_0}{4A_0R}e^{4A_0V/V_0}+C=\frac{1}{4A_0R}(e^{4A_0V/V_0}-1) \tag{45}$$

if $I=0$ when $V=0$. An exponential relation between voltage and current is thus found to be suitable for a lattice-type losser element as well as the shunt and series types. That a function of form (45) can actually be realized over a wide range including bias values near zero is indicated by the curve of $I+0.025$ in figure 1.

It is to be noted from (36) that as V becomes large, the hyperbolic tangent approaches unity, and hence the voltage transfer ratio approaches a constant. The lattice may therefore be used as a *limited range expandor*, that is, to expand small inputs in the ratio of 2:1, while leaving large inputs unaffected. Likewise when placed in the feedback path of an amplifier, the lattice may be used to obtain a 2:1 *limited range compressor*, and a combination of these forms a *limited range compandor*.

Variable-Ratio Device

In figure 5 is shown a device differing from those previously discussed in that the control is on a voltage basis rather than current. The resistance of the varistor combination X_1, X_2 is made small at all times compared with the resistance R_0 and that of the rectifier-filter circuit Y. We therefore have approximately

$$i_a=\frac{V_1}{R_0} \tag{46}$$

Furthermore if the varistors have exponential current-voltage relationships, the voltage v_a across the varistor combination and the current i_a must satisfy the equation

$$|i_a|=\alpha e^{\beta|v_a|} \tag{47}$$

with the additional proviso that i_a is an odd function of v_a because of the oppositely poled pair of elements.* It follows that

$$|v_a|=\frac{1}{\beta}\log\frac{|i|}{\alpha}=\frac{1}{\beta}\log\frac{|v_1|}{\alpha R_0} \tag{48}$$

Now considering the rectifier-filter circuit Y, let the output voltage V be proportional to V_a, the envelope of v_a, and V_a be related to the envelope V_1 of the voltage v_1 in the same manner as v_a and v_1 are related by (48). Then

$$V=gV_a \tag{49}$$

where g varies between 0 and 1, as determined by the setting of the potentiometer P, and

$$V_a=\frac{1}{\beta}\log\frac{V_1}{\alpha R_0} \tag{50}$$

If the voltage V is used as bias on the varistor elements of a vario-losser circuit, with the varistor impedance high enough not to affect the relation between V and V_1 appreciably, we should have, assuming varistor elements which have the same exponential characteristic as (47),

$$i/r=dI/dV=d(\alpha e^{\beta V})dV$$
$$=\alpha\beta e^{\beta V}$$

Hence

$$r=\frac{1}{\alpha\beta}e^{-\beta V}=\frac{1}{\alpha\beta}e^{-\beta g V_a}$$
$$=\frac{1}{\alpha\beta}e^{-g\log\frac{V_1}{\alpha R_0}}=\frac{1}{\alpha\beta}\left(\frac{V_1}{\alpha R_0}\right)^{-g} \tag{51}$$

If the vario-losser is of the shunt type, we have from (6),

$$A=kV_1^{-g},\quad k=1/\alpha\beta Z_1(\alpha R_0)^{-g} \tag{52}$$

Comparing with (3) and (4), we then have the results that for a backward-acting shunt type, $n=1-g$; while for a forward-acting shunt type, $n=1/(1+g)$. Similarly, if the vario-losser is of the series type, we make use of (18) and find

$$A=kV_1^{g},\quad k=\alpha\beta Z_2(\alpha R_0)^{g} \tag{53}$$

whence for forward action, $n=1+g$, and for backward action, $n=1/(1-g)$. Since g may be varied continuously between the limits zero and unity, any positive value of n may theoretically be obtained by choosing from the above four types. The ranges of n available from each type are:

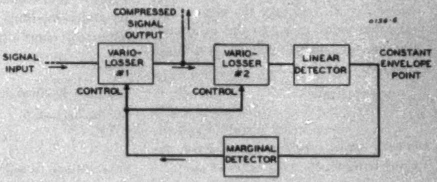
	n	Use
Shunt type, forward acting	0 to 1	Compressor
Shunt type, backward acting	$^1/_2$ to 1	Compressor
Series type, forward acting	1 to 2	Expandor
Series type, backward acting	1 to ∞	Expandor

Marginal-Detector Types

The losser circuits so far described require that the varistor elements have specific current-voltage characteristics, for example, the exponential form, in order to yield the desired mode of operation. It is possible to construct vario-losser circuits to obtain specified ratios of compression or expansion without requiring any property of the varistors other than that of resistance variable with bias. This is accomplished by introducing an auxiliary device, the so-called "marginal detector." A marginal detector may be defined for our purposes as a device which delivers no output when the input is below a certain fixed value, and increases its output very rapidly as the input is increased very slightly through the critical value. A vacuum-tube detector with grid biased negatively beyond the cut-off is an approximation to the ideal marginal detector. If the input of a marginal detector is taken from the output envelope of the signal (see figure 6) and the marginal detector output is used as bias on varistors in a shunt-type vario-losser, no effect occurs when the output is below the marginal value. When the marginal value is exceeded the loss in the shunt varistors increases rapidly with the result that the output cannot appreciably exceed the marginal value. Such an arrangement therefore acts as an envelope limiter.

Now consider the result of using two identical shunt losser circuits in succession as in figure 6 with the same biasing current supplied to each from the marginal detector. The envelope is evidently held constant at the output of the second losser whenever the input to the first exceeds a critical value. Since the two lossers are identical, each must have the same loss. Let x_0 represent the total loss in decibels in the two lossers when the critical input value is not reached. Then if the input to the first losser is x decibels above the critical value, the loss in each of the two lossers is $(x+x_0)/2$ decibels. The output of the first losser therefore increases by $x/2$ decibels when the input increases by x decibels and is therefore compressed in a ratio of 2:1. If three losser units are used instead of two, the output of the first is compressed 3:2 and the output of the second 3:1. In general if n units are used, the output of the mth unit is compressed by the ratio $n/(n-m)$.

Figure 6. 2:1 compressor of marginal-detector type



A 2:1 expandor may be realized by means of two lossers and a marginal detector, as shown in figure 7. The bias must in this case be supplied by the two lossers in such a way that the loss decreases in the first and increases in the second with the increasing bias. If the amount of decrease in the first is made equal to the amount of increase in the second, the output of the first losser is expanded in the ratio of 2:1.

The marginal detector circuits have the obvious advantage of not being limited by the types of varistor characteristics available, but this is offset by the added complication of the marginal detector itself, which may offer a troublesome adjustment and maintenance problem.

Distortion

It is of course necessary for satisfactory operation that the distortion of the signal resulting from transmission through the vario-losser path be held to a low value. Quantitative estimates of the distortion can be obtained by considering the case of a single-frequency input. The envelope then becomes a constant, and the bias applied to the typical varistor element consists of a direct current. The instantaneous voltage across a particular varistor element is the sum of the bias voltage and the voltage produced by the signal. Substitution of this instantaneous voltage in the current-voltage relation for the varistor element enables the approximate calculation of the distorted component of signal current.

We may illustrate by considering the shunt-type vario-losser circuit, figure 2. If the signal input is represented by

$$v_1=V_1\cos pt \tag{54}$$

the signal output is to a first approximation, also sinusoidal and of the form,

$$v_2=V_2\cos pt \tag{55}$$

If all four varistor elements are identical, each with the instantaneous current-voltage relation, $i=f(v)$,

---

* This arrangement is necessary in the case of copper oxide. In the case of silicon carbide, the material itself would have the proper symmetry and one element would suffice.

$$i_a=i_c=f\left(V+\frac{1}{2}V_2\cos pt\right) \tag{56}$$

$$i_b=i_d=f\left(V-\frac{1}{2}V_2\cos pt\right) \tag{57}$$

$$i_d-i_a=f\left(V-\frac{1}{2}V_2\cos pt\right)-f\left(V+\frac{1}{2}V_2\cos pt\right)$$
$$=-f'(V)V_2\cos pt-\frac{f'''(V)}{3!}\frac{V_2^3}{4}\cos^3 pt-\ldots \tag{58}$$

The principal distortion component is thus a third harmonic

$$i_d-i_a=-\frac{f'''(V)}{24}V_2^3\cos^3 pt \tag{59}$$

This current may be considered to be generated in the varistor bridge and to divide between the impedances Z_1 and Z_2. No even harmonics appear in the output circuit because of the assumed balance of the bridge. The third harmonic voltage appearing across the output is

$$v_{23}=-\frac{Z_1Z_2f'''(V)V_2^3}{96(Z_1+Z_2)}\cos 3pt \tag{60}$$

The significance of the negative sign is that the phase of the third harmonic is such as to flatten the peak of a sine wave, which is to be expected since the shunting action of the varistors is greater for large amplitudes. It is convenient to assume $Z_1=Z_2$, and take the ratio of the maximum value of v_{23} to the maximum fundamental output voltage amplitude V_2, giving

$$\frac{V_{23}}{V_2}=\frac{Z_1f'''(V)V_2^2}{192} \tag{61}$$

For a series-type losser, we have, referring to figure 3,

$$i_a=f\left(V-\frac{V_1}{2}\cos pt\right) \tag{62}$$

$$i_b=f\left(V+\frac{V_1}{2}\cos pt\right) \tag{63}$$

$$i_b-i_a=f'(V)V_1\cos pt+\frac{V_1^3f'''(V)}{4.3!}\cos^3 pt+\ldots \tag{64}$$

$$V_{23}=\frac{V_1^3Z_2f'''(V)}{96}=\frac{f'''(V)}{96Z_2^3}r^3V_2^3 \tag{65}$$

$$\frac{V_{23}}{V_2}=\frac{f'''(V)}{12[f'(V)]^3}(V_2/Z_2)^2 \tag{66}$$

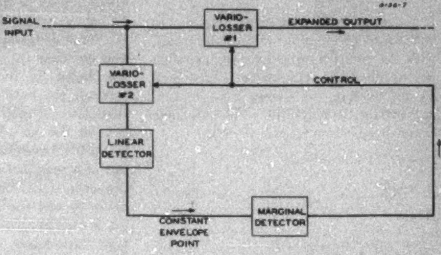


Figure 7. 2:1 expandor of marginal-detector type

The above principles may be illustrated by working out an example. Suppose it is desired to use copper-oxide varistors having the characteristic shown in figure 1 in a shunt-type vario-losser such as shown in figure 2 with third harmonic at least 30 decibels down on fundamental over a 30-decibel range of loss variation. Also given that the maximum amount of direct current per varistor is four milliamperes. It is required to find the maximum output voltage permissible and the impedance which should face the varistors. We assume $Z_1=Z_2$. The characteristic of figure 1 may be represented by the equation

$$I=0.025(e^{2V}-1) \tag{67}$$

where V is in volts and I in milliamperes. By differentiation, we find that the resistance in ohms is given by

$$r=2.10^4e^{-2V} \tag{68}$$

and that the third derivative is

$$f'''(V)=\frac{4}{r} \tag{69}$$

Substituting in equation 61, we find for the ratio of third harmonic to fundamental,

$$\frac{V_{23}}{V_2}=\frac{0.0208Z_1V_2^2}{r} \tag{70}$$

The greatest distortion occurs at the maximum load. Calling the maximum output voltage V_{20}, and noting that distortion 30 decibels down is equivalent to a voltage ratio of 0.0316, we write as one requirement:

$$\frac{Z_1V_{20}^2}{r_0}=1.53 \tag{71}$$

The required 30-decibel variation in loss is to be obtained as r is increased from the minimum permissible value specified by (71) to its maximum value, which occurs with zero bias. If we assume that the maximum value of r is large compared with Z_1, we see from (5) and (6) that the value of A varies from $^1/_2$ to r_0/Z_1. The total variation in loss is therefore 20 $\log_{10}$ $2r_0/Z_1$, and if this is to be 30 decibels we must have

$$r_0/Z_1=0.0158 \tag{72}$$

Substituting (72) in (71), we find $V_{20}=$ 0.155 volt. Since the bias current I_0 available for each varistor at this value of V_{20} is four milliamperes, the corresponding voltage V_0 across each varistor is, from figure 1, 2.5 volts, and from (68), the resistance r_0 is 132.5 ohms. From (72), the terminating impedance Z_1 should be 8,390 ohms.

Possibilities and Methods of Extending a Carrier Current Relay Channel to Other Uses

R. M. SMITH
ASSOCIATE AIEE

S. L. GOLDSBOROUGH
ASSOCIATE AIEE

CARRIER-CURRENT relaying is now well established as the most complete type of protection. It has had sufficient field experience to well justify the fundamental principles on which it is founded and the manner in which it has been worked out. As it often happens, the solution of one problem will lend itself to another similar problem. This seems to be the case of carrier-current relaying as it has provided the communication channel which might be available to solve other problems involving the transmission and reception of signaled information. This common solution to two problems naturally lessens the economic factors which relieves each problem of the strain of carrying the entire burden. Other problems involving the use of communication means which could be provided by the relay channel are: telemetering, supervisory control, load control, communication, remote tripping, etc. The addition of these other functions to the carrier channel, while not involving serious technical difficulties, nevertheless, requires the consideration of some problems. Methods are available and actual installations have been made involving various combinations of additional uses of the relay channel.

While the accommodation of several quantities on the carrier channel may seem to violate the old adage that two bodies cannot occupy the same space at the same time, nevertheless, the telephone industry has shown for a number of years that several separate sets of information-carrying quantities can occupy the same transmitting medium. There are two aspects of the problem of extending the functions of a carrier-current relay channel involving different degrees of complication. One method is to add functions but not require that they be carried on at exactly the same time. This way lessens the amount of apparatus required but introduces the necessity for compromises in the desired characteristics. There are a large number of combinations of functions which can be added to the relay function without materially adding to the equipment provided they are co-ordinated and compromised in the right manner. The manner in which the problem is solved is specific for each application. It is not the purpose of this paper to consider all of these combinations but merely to point out some of the possibilities.

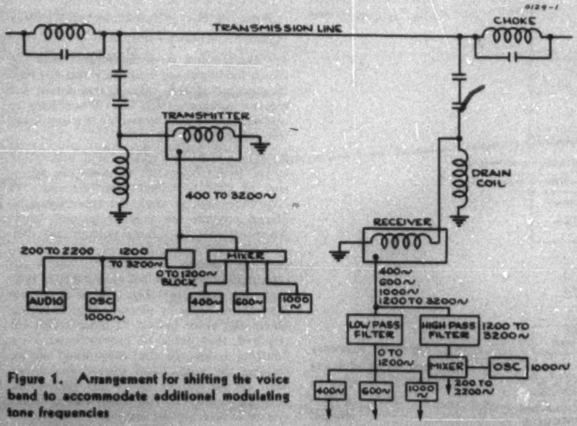

Figure 1. Arrangement for shifting the voice band to accommodate additional modulating tone frequencies

The other method assumes that all the functions performed by the carrier channel must be carried on concurrently. This means that additional equipment must be provided to render the functions entirely independent of one another and, of course, removes the necessity of imposing any restrictions or compromises.

Fundamental Problems

There are a number of fundamental requirements which must be considered in any scheme to extend the use of a relay channel. Since the primary object of the carrier channel in a relay system is to transmit information between the relays at the ends of the protected section, the relays must be capable at all times of starting and stopping the carrier signal regardless of whatever other use is being made of the carrier wave. Any other use of the carrier channel must be temporarily suspended during the occurrence of faults on the system. Ordinarily, this should not seriously interfere with the additional functions since with high-speed relays the time of interruption is small. The loss of a few telemetering impulses or a syllable of speech would hardly be considered serious. Even the interruption occasioned by slow-speed relays clearing a fault elsewhere on the system is not serious. This preferential use of the carrier channel by the relays can always be attained in systems where all of the carrier functions are entirely independent but in systems where compromises are made for the sake of simplicity there may be times when the relays are unable to take control of the carrier. An example is the case where no fault current flows at one end of the line. Here a telemetering impulse or telephone conversation could prevent tripping because there is no relay action at the zero current end to stop the carrier.

There are two ways in which the relay carrier channel can be extended to other uses.

1. The carrier wave itself may be used to carry the intelligence. This method requires the least amount of additional equipment but has limitations in the number of

functions that can be handled. Telemetering can be added by merely "keying" the carrier to send out a set of impulses in which either the rate or the duration of the pulses are used to actuate the telemetering receiver. Communication alone can be easily added, since it requires merely that the carrier be held on continuously. However, communication and telemetering could not be accomplished simultaneously since the one function requires continuous and the other requires impulsed carrier. Furthermore, more than one telemetering quantity cannot be used, since the impulses would interfere.

In general, it may be said that if the carrier wave itself is employed, it can take care of only one additional function at a time. If the additional functions do not need to be performed at the same time, then several purposes can be served by the relay carrier channel. Thus, communication, telemetering, supervisory, and remote tripping could be accomplished.

The chief disadvantage of utilizing the carrier wave itself is, as was indicated previously, the possibility of preventing tripping when no fault current occurs at one terminal. In this case, the carrier, if initiated by communication, telemetering, etc., at the end where no fault current flows, cannot be stopped by the relays at this end.

2. A number of tone or modulating frequencies may be imposed upon the carrier and each tone may be used to transmit a separate set of signals. If the tone frequencies are not inside the voice frequency band, communication may also be added. Also, if the relay signal is placed on one of the tones instead of the carrier itself, the difficulty experienced when no fault current flows initially at one terminal is entirely avoided. Assuming that communication is not desired, the number of functions which can be accommodated is limited only by the number of tone frequencies which can be placed in the audio band width which the carrier set will pass. With communication the number of functions is limited by the number of tones that can be placed outside an intelligible voice band but inside the band capable of being passed by the transmitter-receiver set.

The use of a tone frequency means that the carrier wave is modulated by one or more definite audio frequencies, say, 600 and 1,000 cycles. At the receiver end the carrier is demodulated and the tone frequencies are separated by filter circuits. It is obvious that each tone may be used to transmit signals entirely independent of all other tones and this system is, therefore, applicable where the number of additional functions cannot be accommodated by the carrier wave itself.

Tone Modulating System

Some of the technical aspects of the tone system are as follows:

1. There must be a minimum ratio between the impulsing frequency and the tone frequency. If this ratio is too small, the receiver apparatus will have a tendency to respond to the tone as well as the impulsing frequency.

2. There must be a wide enough separation in the tone frequencies to avoid the necessity of sharply tuned filter circuits. If communication is used, the tones must be placed outside the voice-frequency band. An intelligible voice band is from, say, 200 to 2,200 cycles and the band which can be ordinarily passed by the carrier set is approximately 200 to 3,200 cycles. It is thus seen that not more than one or two tone frequencies could be placed either below or above the voice band. If more tones are required, they could be provided either by "cutting holes" in the voice band or by shifting the voice band toward the upper limit of the carrier set. The process of "cutting holes" in the voice band would consist of filtering out say from 900 to 1,100

cycles from the voice input to the modulator and then supplying a 1,000-cycle note from an audio oscillator. The absence of the 900 to 1,100-cycle notes would have some tendency to impair the speech quality and, of course, if too many of these holes were cut, the speech would become too poor for intelligible use.

Another method for accommodating speech and tone frequencies would be to shift the voice frequency toward the high end of the receiver band. Assuming 200 to 2,200 cycles sufficient for clear speech, this could be shifted to 1,200 to 3,200 cycles by adding 1,000 cycles. This would give a band of say 100 to 1,200 cycles for tone frequencies. Possible tones of 100, 130, 170, 220, 286, 370, 480, 620, 810, 1,050 could be accommodated with a 30 per cent separation below 1,200 cycles. Figure 1 shows schematically the arrangement needed to accomplish this system. The speech input is heterodyned with the output of a 1,000-cycle oscillator and the sum frequency is passed into the carrier set modulator. A high-pass filter cuts off all frequencies below 1,200 cycles. Separate oscillators producing different tones also feed through a mixing device to regulate the amplitude into the carrier set. At the receiving end frequencies up to 1,200 cycles are first filtered out, leaving the voice band 1,200 to 3,200 cycles from which 1,000 cycles is subtracted by heterodyne action with a 1,000-cycle oscillator. The output of the low-pass filter is further filtered into the individual tones.

To our knowledge, no application of this voice-shift system has yet been made in this country, but it has been used in France.[1] The chief object here is to point out the engineering aspects involved in connection with a very extensive additional use of a carrier relay channel. Figure 2 shows an extensive use of tone frequencies on a carrier-current channel on which communication is not desired.

Telemetering

It is the purpose here to discuss some of the specific problems which occur when the telemetering function is added to the relay carrier channel. There are two types of impulse telemetering systems. One takes account of the rate of the impulses and the other operates on the duration and spacing of impulses. The problems discussed here are based on the system utilizing the rate of impulses. The same problems could, no doubt, be solved in a similar manner for the impulse duration principle. Also, it should be understood that each application of telemetering to a relay carrier channel may involve specific problems requiring a solution applying only to that application and it is not the intention here to cover all of the problems which might arise. Furthermore, no attempt is made here to discuss telemetering systems themselves.

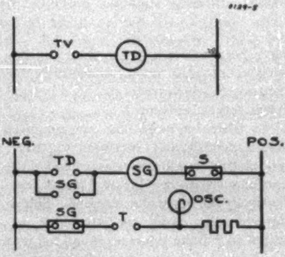

Figure 5. Scheme to stop telemetering from the receiver end

Figure 3 shows schematically a relay carrier scheme.[2] The carrier is initiated by the closure of the impedance or overcurrent contacts, *Z* or I_0, which impresses negative potential on the oscillator cathode. Carrier is stopped when the directional and impedance contacts, *D* and *Z*, close to energize the *CSP* coil which in turn opens the *CSP* contact, thus returning the cathode to positive. Carrier is started and stopped in a similar manner by the action of the ground relay contacts, D_0 and I_0. The telemetering contact is placed in parallel with the *Z* carrier start contact and it is obvious that with this connection the relay contacts can start and stop carrier regardless of what position the telemetering contact is in. At the receiving terminal a relay is placed in the plate circuit of the receiver tube and is actuated by each of the carrier pulses. The contacts of this relay are connected to actuate the telemetering receiver.

At both the sending and receiving terminals there is an alarm relay, *AL* whose function is to close contacts when a carrier signal is received and ring an alarm bell. The primary purpose of this alarm bell is to enable the operators at each end of the line to signal each other when it is desired to test the transmission and reception of carrier or to communicate by telephone. Obviously, if telemetering signals are being transmitted, it would be

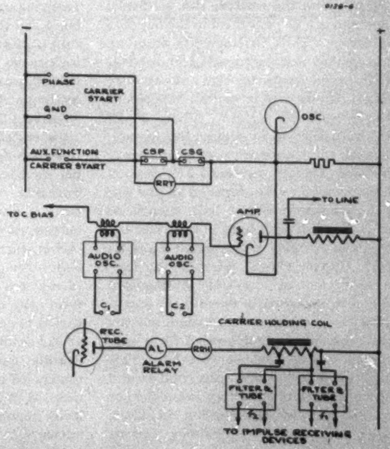

Figure 6. Schematic diagram of modulating tone frequencies

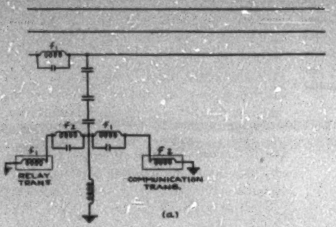
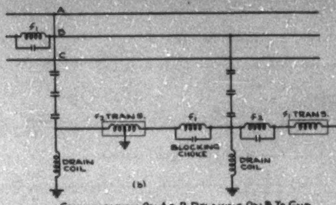
Figure 7



Relaying & Communication One Phase Wire To Ground

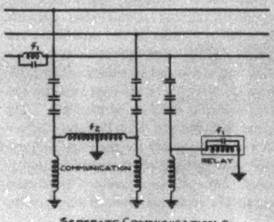


Communication On A & B Relaying On B To Gnd.

confusing to ring the alarm bell on each signal. Of course, a simple solution is to disconnect the bell, but this prevents the bell from performing its normal signaling function.

An arrangement to prevent the alarm relay from operating on telemetering impulses but permit it to operate when it is desired to signal is shown in figure 4. During the reception of telemetering signals the alarm relay coil, *AL*, is short-circuited by the *X* contact operated by the *X* relay which is energized through the resistors, R_1 and R_2, and the *TV* back contact. The *TV* relay operates on each carrier impulse and opens its back contact, but the *X* coil is energized by the capacitor discharge until the *TV* contact closes again. When it is desired to operate the alarm bell the carrier is held on at the remote station for approximately one second. This opens the *TV* contact and after the capacitor has discharged, the *X* relays drops out, thus allowing the alarm relay, *AL*, to pick up on the carrier signal.

Another problem which arises is the necessity of stopping the transmission of signals, from the receiver end, so that a function can be performed in the opposite direction. Thus, telemetering from an unattended station to an attended station may be stopped so that a supervisory signal may be sent to control breakers at the unattended station. Figure 5 depicts a scheme to accomplish this feature. During the transmission of telemetering impulses the relay contacts, *TV*, close on each impulse. The duration of the impulse, however, is not long enough to allow the time delay relay, *TD*, to pick up, thus the *SG* relay is de-energized and its back contact closed, allowing the telemetering contact, *T*, to transmit impulses. When it is desired to operate the supervisory from the attended station, the carrier push button is depressed for a long enough time to close the *TD* relay. This picks up the *SG* which seals itself in and opens its back contact to prevent further transmission of telemetering impulses. After the desired supervisory actions have been performed, the final supervisory action is to open momentarily the contact, *S*, which resets the *SG* relay and telemetering is resumed.



Seperate Communication & Relaying Channels
(c)

To telemeter more than one quantity simultaneously, it is necessary to "key", modulating tone frequencies instead of the carrier wave itself. Figure 6 shows schematically the apparatus required. Simple vacuum-tube audio oscillators are adjusted to definite frequencies and fed into the grid of the amplifier tube. At the receiving end the carrier wave is demodulated and the plate circuit of the receiver tube contains the tone frequencies. These frequencies are separated and fed to the telemetering receiver devices. At the sending end the audio oscillators are impulsed by the contacts, C_1 and C_2, which are operated by the telemeter transmitter. If signals are sent continuously, the carrier wave must, of course, be held on continuously. If the signaling is intermittent, it would be possible to have the telemetering transmitter also operate the carrier start contact.

Another principle which has been used to enable a single carrier channel to perform more functions and avoid complication is to store the telemetering impulses at the sending end and transmit only at definite intervals. The impulses are merely fed into a mechanical counter and then at regular intervals the accumulated impulses in the counter are transmitted.

Supervisory and Remote Tripping

There are numerous combinations of supervisory, telemetering, and remote tripping which can be applied to a relay carrier-current channel. For instance, the telemetering can be made one point on the supervisory control.

Where supervisory control is installed, it is generally important enough to demand a good pilot circuit. Certain troubles with conventional pilot circuits have brought out the fact that a high-voltage line is not only reliable as a power distributor, but is also just as reliable as a pilot wire. For this reason carrier-current channels over the high-voltage line itself are more and more being used for supervisory control.

In general, supervisory control requires the transmission of signals in both directions. However, these signals do not need to be sent simultaneously, and therefore, a single-frequency relay carrier channel is all that is required. It is possible to combine the supervisory system with other functions without complication by making the other functions merely points on the supervisory system.

A relay carrier channel provides an excellent means of tripping a distant breaker when the fault current is too small to actuate the protective relays. A practical example is the case where a transformer bank is included as part of the high-voltage line with no high-voltage breaker. The problem here is to protect the transformer against internal faults which may not draw enough current from the distant end to actuate the line relays. With a carrier channel available, sensitive differential protection can be applied to the transformer, and the tripping of the distant breaker can be initiated by the transmission of a carrier signal. Of course, the local low-voltage breaker is tripped directly by the differential relays. One company in New England has installed this remote tripping scheme on a carrier-protected line which includes a transformer bank at one end and has had successful results. The differential relays trip the local low-voltage breaker and also cause a coded signal to be sent via the carrier to trip the breaker at the other end of the line. The use of a coded set of carrier impulses eliminates possible trippings on stray interference. The transmission and reception of the code signal required about one-third second. Faster action could be obtained by using one or more modulating tone frequencies instead of applying impulses to the carrier wave itself.

Communication

In applying communication to a relaying carrier-current channel, it should be realized that the carrier channel is primarily for relaying purposes and was not designed as a communication channel. A high-quality communication channel requires a number of characteristics which a relay carrier transmitter-receiver does not possess. When the communication requirements as to quality, distance, number of talking points, etc., become important, it is usually more economical and satisfactory to divorce the communication from the relays by providing a separate channel. In some cases, it is possible to obtain the channel separation but still make some of the apparatus serve both relays and communication.

However, for moderate communication requirements, the relay carrier equipment lends itself admirably to communication purposes. One relay carrier transmitter-receiver has a built-in modulator for this purpose. The type of communication ordinarily provided by a relay carrier channel is known as the "point-to-point-push-to-talk" method. That is, an operator at one station first signals the operator at another station by means of the carrier push button and the alarm bell. After contact has been made, the operator wishing to talk presses a button on the handset to cause carrier transmission. After he is through, the operator at the other end of the line must depress his handset button in order to reply.

Communication on a relay carrier channel is necessarily limited to point-to-point because the relay scheme requires that each line section operate on a frequency of its own, isolated from other sections. Communication through a line sectionalizing point means that the carrier must be by-passed around the station. Obviously, a relay carrier channel cannot be handled this way. It has been suggested that several line sections be coupled together for communication on the relay carrier channel by repeating the voice frequencies around the substation. Such an audio by-pass can be arranged, but a complication introduced is the cascading of the receiver distortion. With several sections coupled in this manner the speech would be unintelligible. Not more than two line sections can be coupled together and still retain a fair quality of speech.

If the importance of the communication function requires operation from several locations, selective calling, and other telephone requirements, then it becomes more economical to provide a separate communication channel and a communication carrier set rather than attempt to adapt a relay carrier channel to this purpose.

In providing an additional carrier channel for communication, some savings may be affected on higher-voltage lines by using a common coupling capacitor to connect the two carrier channels to the high-voltage line. Both relay and communication channels can be on one phase-to-ground, or the communication can be phase-to-phase and the relay channel phase-to-ground. Figure 7*a* shows relaying and communication on one phase-to-ground using one coupling capacitor. No line chokes are shown for the communication frequency, since they are not necessary unless the distances and number of line paths over which the carrier can divide are too great. Figure 7*b* shows the communication phase-to-phase and the relay carrier channel phase-to-ground. Here it is necessary to provide one extra coupling capacitor for the communication. Phase-to-phase communication is more efficient and encounters a lower noise level than phase-to-ground coupling and is generally used where the communication covers a large area.

Conclusions

1. Definite economies can be effected by using a relay carrier channel for other uses. These additional uses will sometimes justify the expense of a relay carrier-current installation.
2. Other functions can be added without much complication, if it is not necessary to perform them simultaneously.
3. Simultaneous performance of two or more functions requires that modulating tone frequencies be provided.
4. The addition of telephone communication limits the number of modulating tone frequencies available for other functions. It is possible to shift the voice-frequency band to accommodate more tone frequencies.
5. If more extensive telephone communication than "point-to-point" is desired, it should be placed on a separate carrier channel.
6. Two separate carrier channels can utilize common coupling capacitors.

Power-Factor Testing of Transformer Insulation

J. B. HODTUM
MEMBER AIEE

Synopsis: This paper points out a method for analyzing the results obtained from dissipation-factor tests of transformer insulation. Experimental data, obtained both from transformer tests, extending over the past three years, and from tests of sample insulation, indicate a definite relation between resistance and capacitance, with varying conditions of temperature and moisture. This relation furnishes an additional means for determining the condition of insulation when considered with other accepted methods.

The physical arrangement of the transformer windings, and the type of test equipment used, affect the tests and should be considered when interpreting results.

THE term, "power-factor testing" of insulation during the past several years has come into wide use. However, it is felt that the use of the dissipation factor is better because it can be more readily determined and is more convenient to use. Dissipation factor is the cotangent of the angle between the voltage and current while power factor is the cosine of the angle.

Equivalent Insulation Circuits

The electrical characteristics of insulation can be represented in the simplest form, for any given frequency, by an equivalent circuit consisting of a single lumped resistance and a single lumped capacitance. The lumped resistance and capacitance may be arranged either in series or in parallel (see figures 1 and 2). However, for this analysis the parallel equivalent circuit has certain advantages over the series circuit and will, therefore, be used throughout.

Since capacitance bridges used for insulation testing read capacitance in terms of the series equivalent circuit, it is necessary to convert these readings to the corresponding resistance and capacitance components of the parallel equivalent circuit. Table II shows the operations necessary to obtain the equivalent parallel resistance and capacitance from the readings of several types of commercial instruments. It will be found that for low values of dissipation factor, the parallel capacitance is approximately equal to the series capacitance. As the dissipation factor increases, however, the difference between the parallel capacitance and the series capacitance increases so that a conversion is necessary for the larger values of dissipation factor.

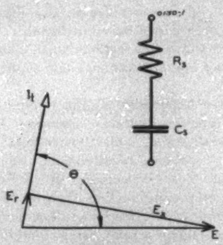

Figure 1. Equivalent series circuit of the insulation

$$\text{Dissipation factor} = \frac{2\pi f C_s R_s}{10^6}$$

When $f = 60$ cycles, C in micromicrofarads, R in megohms:

$$\text{Dissipation factor} = \frac{C_s R_s}{2{,}650}$$

Physical Arrangement of Windings

Transformer windings are grouped in various arrangements depending upon the kilovolt-ampere rating, the voltage and the impedance requirements, and whether of shell- or core-type construction.

Figures 3, 4, and 5 show typical winding arrangements or groupings for two winding transformers and the equivalent circuits of such transformers as composed of three major parts as follows:

1. Insulation between high-voltage winding and ground designated by subscript *a*.

2. Insulation between high-voltage winding and low-voltage winding designated by subscript *b*.

3. Insulation between low-voltage winding and ground designated by subscript *c*.

It is recognized that resolving the insulation structure into these very simple forms does not always give a complete picture but this division is used because of its simplicity.

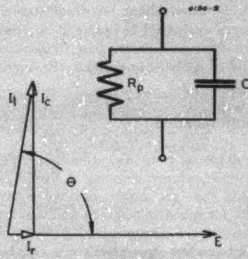

Figure 2. Equivalent parallel circuit of the insulation

$$\text{Dissipation factor} = \frac{10^6}{2\pi f C_p R_p}$$

When $f = 60$ cycles, C in micromicrofarads, R in megohms:

$$\text{Dissipation factor} = \frac{2{,}650}{C_p R_p}$$

If the measuring instrument used contains a guard circuit these individual parts of the insulation may be tested directly.

When a guard circuit is not available, it is then necessary to conduct the following three tests:

Test *A*—High-voltage winding to low-voltage winding and ground.

Table I. Separated Capacitance and Resistance Components for Equivalent Circuits of Figures 3, 4, and 5

From Tests A, B, and G	For Figure 3	For Figure 4	For Figure 5	Part of Insulation
$\frac{1}{2}(C_A+C_G-C_B)=$	C_a+C_a'	C_a'	C_a+C_a'	High voltage to ground
$\frac{1}{2}(C_A+C_B-C_G)=$	C_b	C_b	C_b	High voltage to low voltage
$\frac{1}{2}(C_B+C_G-C_A)=$	C_c+C_c'	C_c+C_c'	C_c'	Low voltage to ground
$\frac{1}{2}\left(\frac{1}{R_A}+\frac{1}{R_G}-\frac{1}{R_B}\right)=$	$\frac{1}{R_a}+\frac{1}{R_a'}$	$\frac{1}{R_a'}$	$\frac{1}{R_a}+\frac{1}{R_a'}$	High voltage to ground
$\frac{1}{2}\left(\frac{1}{R_A}+\frac{1}{R_B}-\frac{1}{R_G}\right)=$	$\frac{1}{R_b}$	$\frac{1}{R_b}$	$\frac{1}{R_b}$	High voltage to low voltage
$\frac{1}{2}\left(\frac{1}{R_B}+\frac{1}{R_G}-\frac{1}{R_A}\right)=$	$\frac{1}{R_c}+\frac{1}{R_c'}$	$\frac{1}{R_c}+\frac{1}{R_c'}$	$\frac{1}{R_c'}$	Low voltage to ground

Test *B*—Low-voltage winding to high-voltage winding and ground.

Test *G*—High-voltage winding and low-voltage winding to ground.

From these tests, the values of *R* and *C* of the separate parts of the insulation may be calculated using the relations shown in tables I and II.

Table I shows that the coil grouping materially affects the results and must therefore be considered in the analysis. It will be noted that the capacitance and the resistance components of the high-voltage winding to ground test of figure 4 is a measure of the high-voltage bushings, leads, and terminal boards to ground rather than high-voltage winding to ground. Such cases can usually be detected from the abnormally low values of capacitance for the high voltage winding. A similar case develops in the low-voltage-to-ground reading of figure 5. The circuit, in such cases, may be composed almost entirely of leakage resistance to ground and may have a high dissipation factor without indicating an abnormal condition.

Measuring Equipment

Available testing equipment for conducting dissipation factor tests is of two general types:

1. Instruments which measure the volts applied, the charging current and the loss.
2. Capacitance bridges which measure the equivalent series capacitance and the dissipation factor.

Table II shows the conversion to equivalent parallel capacitance, parallel resistance, and dissipation factor for each type of instrument. This conversion must be recognized in order to place all data on the same basis of parallel resistance and parallel capacitance.

Results

The results of more than three years of testing have definitely indicated that insulation of low moisture content shows a reduction in its a-c resistance with increasing temperature, the capacity part of the circuit remaining practically constant. For wet insulation, on the other hand, increasing temperature has been found to produce a considerable increase in capacitance as well as a reduction in the a-c resistance.

Dry insulation, therefore, has the highest value of a-c resistance and the lowest value of capacitance. As moisture is absorbed, the first change appears in a reduction of the resistance. Further increase in moisture content at constant temperature increases the capacitance along with a more gradual reduction in resistance.

Figure 6 shows this relation, and the predicted change in dissipation factor, at constant temperature, for varying amounts of moisture.

Figure 7 shows the relation between *R* and *C*, for both wet and dry insulation, over the temperature range of 20 to 75 degrees centigrade. This curve is an attempt to show the approximate limits for thoroughly dry insulation and for insulation containing approximately 40 per cent moisture.

Figure 8 shows the relations between temperature and dissipation factor for wet and for dry insulation. It is interesting to note that the dissipation factor for dry insulation increases for increasing temperature faster than for wet insulation. This means that for a known dissipation factor at one temperature, it is not possible to predict what it will be at another temperature, unless the insulation is known to be dry.

2. Capacitance bridge	C_s and DF	$\frac{2,650}{C_p \times DF}$	$C_s \times \sin^2\theta$	From bridge

Note: Express *E* in kilovolts, *I* in milliamperes, *W* in watts, *R* in megohms, *C* in micromicrofarads, *θ* in degrees (power-factor angle).

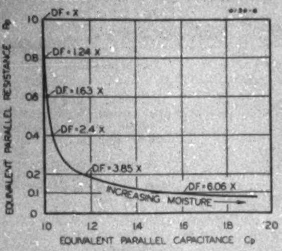

Figure 6. Relation between R_p and C_p for constant temperature and increasing moisture content

Figure 9 shows the changes of R and C for wet and dry insulation as a function of temperature. These characteristics furnish the means for determining the condition of the insulation from the moisture standpoint, since the capacitance component for wet insulation increases much more rapidly than for dry insulation with increasing temperature.

Analysis

To determine the condition of transformer insulation where high dissipation factors are encountered, it is suggested that in addition to the usual checks, such as tests on the oil and Megger tests, dissipation-factor tests be conducted at more than one temperature, and that these tests be separated into the R and C values of the component parts. If the tests do not show an appreciable increase in C for the higher temperature readings, the insulation is relatively moisture free, while if C shows a considerable increase for any one of the separated values, the presence of distributed moisture in that part of the insulation is probably indicated. Corrective measures then consist of either drying the insulation or of reconditioning by other means.

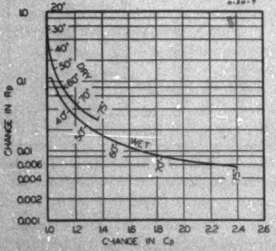

Figure 7. Relation between R_p and C_p for constant moisture content and increasing temperature

Several cases have presented themselves of transformers having high dissipation factors which when tested at two different temperatures did not show an increase in capacitance at the higher temperature. To check this condition, the units were placed in a drying oven for more than 400 hours, part of the time under vacuum. During this time the capacitance did not change and the cause of the high dissipation factor was traced to the transformer oil. When the oil was replaced, the dissipation factor tested normal.

In another case tests conducted on a series of small transformers of the same design, showed variations in the dissipation factor. The winding arrangement of these units was similar to figure 3. When the test results were analyzed all of the variations appeared in the R_b and R_c values, both of which are made up of solid insulation. The R_a value, principally a test of the oil, remained constant. Since these variations were only in the resistance values of the solid insulation, it would indicate slight differences in the drying-out procedure.

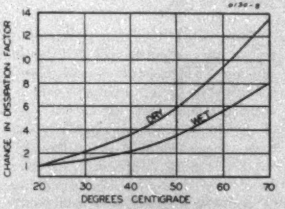

Figure 8. Change of dissipation factor with temperature

An analysis of dry-out runs made in oil have shown, by separating the values, that parts of the insulation sometimes have more moisture in them after the dry-out than they had before, although the over-all dissipation factor was lower. This would evidently indicate a migration of the moisture from one part of the winding to another and that the dry-out run had not been completed.

Cases where the resistance is abnormally low, without a corresponding increase in capacitance, indicate a local low resistance path rather than distributed moisture.

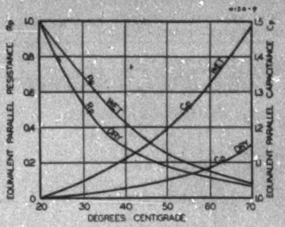

Figure 9. Change of R_p and C_p with temperature

It is recommended that when high voltages are used for conducting these tests, the test voltage be less than the rated voltage of the winding. If higher than rated voltages are used, additional losses, such as for example, the corona loss in the bushings or other parts, may affect the readings and obscure the true condition of the insulation itself.

From this, it is suggested that the results of tests conducted at more than one voltage may be used to detect the presence of corona.

Conclusions

Tests have indicated that when properly applied, dissipation-factor testing, in connection with other accepted tests, may be useful in determining the condition of insulation and sometimes the location of the defective part may be actually determined. It is also possible to determine whether the high dissipation factor is due to moisture or to other cases, which drying out would not improve.

No conclusions have, as yet, been reached regarding the extent to which the resistance may decrease without an appreciable increase in the capacitance before the insulation is considered unsafe from a moisture standpoint. For example: assuming a dissipation factor of X (figure 6), it will be seen that the resistance may drop to 0.4 of its dry value, at the same temperature, with only a slight increase in C, but with an increase to $2.4X$ in the dissipation factor. A change of this order may not be objectionable as it still lies in the vertical part of the curve, indicating only a small increase in moisture content for the higher dissipation factor.

Discussion

Discussion will be found in the 1941 annual TRANSACTIONS volume and in the June 1941 SUPPLEMENT to ELECTRICAL ENGINEERING—TRANSACTIONS SECTION.

Investigation of Starting Requirements of a 660-Horsepower Locomotive Diesel Engine

JOHN C. DAVIDSON
ASSOCIATE AIEE

R. LAMBORN
ASSOCIATE AIEE

PRIOR to 1926 the starting of railway-type Diesel engines was generally accomplished by the use of compressed air. This method of starting had certain disadvantages in locomotive operation, and in an effort to overcome them, a trial installation was made of an electric starting system. This involved the application of a 56-cell lead-acid type storage battery and the addition of a special series winding in the main generator of the locomotive, through which the battery current was passed when starting, causing the generator to function as a series-wound motor. Since that time this method has been used successfully on practically all Diesel-electric locomotives.

Much of the application work in succeeding years was done on an empirical basis; more recently it was felt that a definite analysis of the conditions governing starting should be made on a railway-type Diesel engine. Tests were desired that would permit determination of (*a*) the maximum torque required to turn the engine over against compression, (*b*) the torque and speed at the moment the engine begins to fire, and (*c*) the elapsed time from the closing of the cranking power circuit until the engine begins to fire, for the conditions of a cold, a normally hot, and an abnormally hot engine.

Equipment

The major items of equipment used for the test were an American Locomotive Company 660-horsepower 700-rpm six-cylinder four-cycle, 12$^{1}/_{2}$-inch by 13-inch Diesel engine, a direct-connected General Electric *GT*-551 traction generator, and a 56-cell *MVMT*-13 Exide Ironclad battery to supply power to the generator for cranking the engine.

Some of the technical difficulties involved in making an investigation of this nature may be readily anticipated, permitting appropriate steps to be taken for their successful solution, while the existence of still other problems may not even be suspected until after a large amount of test data have been worked up and carefully analyzed. The determination of the torque delivered by the cranking motor to the engine, and the engine speed, fall into the former classification.

Because of the pulsating nature of the compression torque of a Diesel engine, it is to be expected that the cranking torque and the speed during cranking will also be pulsating in nature. In the case of a six-cylinder four-stroke-cycle engine, there are three compression strokes per revolution, resulting, at 100 revolutions per minute, in a pulsation frequency of 300 cycles per minute or 5 cycles per second. Recording meters are entirely unsuited for making measurements of this nature because of the high inertia of their moving systems and because of the limitations in the performance of their recording stylus on the chart. The conventional multielement permanent-magnet oscillograph is the ideal measuring and recording instrument for the purpose.

Having determined the necessity of using an oscillograph in the investigation, we must consider what quantities to measure and record. In this respect, the determination of the torque input to the Diesel engine presents the greatest problem. It would be most desirable to determine and record it directly by means of one of the various strain measuring methods, but unfortunately this cannot be done because of the closeness and rigidity of coupling between the generator and engine. In view of this, the most practical method seemed to be the use of the generator itself as a dynamometer. Since it is connected as a simple series-excited motor during the engine cranking period, it is necessary to measure only a single electrical quantity, current input, to permit a quite accurate determination of the torque developed. The few minor loads supplied by the battery while cranking the engine are entirely insignificant compared to its input to the generator; hence the addition of a battery voltage trace to the oscillograph record will permit determination of the battery volt-ampere discharge characteristic. Recording the armature voltage of a small separately excited shunt generator, direct connected to the engine generator set, was chosen as the best and most convenient method of determining engine speed. A 60-cycle voltage wave was also recorded to serve as the basis for all time measurements. Thus, four oscillograph elements were required and arranged to indicate:

A—Battery current
B—Battery voltage
C—Generator speed
D—Time (60-cycle wave)

Test Procedure

Preparatory to the first cranking test, the Diesel engine was warmed up to average operating temperature as indicated by a radiator water temperature of 120 degrees Fahrenheit. Then, after a shutdown of approximately five minutes and at a prearranged signal from the oscillograph operator, the engine starting button was pressed. This start button closed magnetically operated contactors between the battery and the generator, and was held in, maintaining this connection, until the engine was audibly running under its own power. This procedure was followed for each of the four succeeding starts, each time using four cells less of the battery. Oscillograph records designated as tests 1, 2, 3, 4, and 5 in the following tabulations were taken using 56, 52, 48, 44, and 40 cells of battery, respectively.

Following this series of normal-engine-temperature starts, the battery was once more restored to its usual 56-cell connection, and the engine operated under load with radiator fans shut down until an engine water temperature of 180 degrees Fahrenheit was obtained. An oscillograph record designated as test 6 was then taken in the manner described above except that the shutdown preceding the start was of only three minutes instead of five minutes duration, in order to prevent too great a loss in engine temperature, which would have defeated the attempt to obtain the cranking characteristics of the engine while abnormally hot.

Following completion of the day's testing, the water was drained from the engine and radiator system and the

locomotive moved out of doors and left to cool down. During the night the outdoor temperature varied between 12 and 22 degrees Fahrenheit. The engine and generator were completely exposed to the wind and weather during this time, as the hood which normally covers this apparatus had not yet been installed. In the morning the locomotive was pushed indoors, the radiator system filled with cold water, and the oscillograph reconnected before proceeding with the cold series of tests. These were made in the same manner as the normal-engine-temperature tests, except 8 cells of battery were cut out between starts, oscillograph records designated as tests 7, 8, and 9 being taken using 56, 48, and 40 cells of battery respectively.

In addition to the oscillograph records, readings were taken from time to time, of radiator-water temperature, lubricating-oil temperature, also battery-electrolyte temperature and specific gravity.

Results

The nine oscillograms taken under conditions as just described have yielded the data shown in table I, which shows the mechanical quantities of torque and speed which these tests were undertaken to determine, also the electrical quantities of amperes (from which the basic uncorrected torque figures are obtained) and volts. Unfortunately, the existence of a calibration error in oscillogram number 1 rendered a portion of its data inaccurate, which accounts for the blank spaces in the tabulation.

The oscillogram of test number 4 reproduced in figure 1 is typical of the records obtained. Various explanatory notes and lines have been added to the original record to aid in tying it in with the values entered in the table of data just mentioned.

However, before attempting a step-by-step interpretation of how the desired information can be obtained from the traces on such an oscillogram, it is desirable to consider for a moment the sequence of events as they take place during the cranking period:

1. As the engine stops preceding the start under consideration, it rocks back and forth several times, finally coming to rest near one of three equally spaced angular positions as determined by the action of the various cylinders which operate in turn as air motors and air compressors.

2. From this position of rest, the engine is rapidly accelerated when the cranking circuit is closed. As the first compression stroke will be only a partial one, the maximum compression torque will be less than usual, and the electrical torque of the starting motor may readily be sufficient to continue accelerating the engine as it turns through the position corresponding to the first peak of torque demand.

3. As the first piston goes over dead center, the air motor action in this cylinder aids the starting motor in further acceleration of the engine.

4. As the second compression peak is approached (first full compression stroke), the rotating system decelerates and its stored kinetic energy is released, thus aiding the starting motor. Deceleration must of course cease and acceleration again take place if the engine is to keep on turning over. At this particular instant of zero acceleration, when the rotating inertia effects are zero, the net torque developed by the starting motor is all delivered to the Diesel engine. The tests indicate that this is the maximum torque output required of the starting motor by the Diesel engine at any time during the starting period.

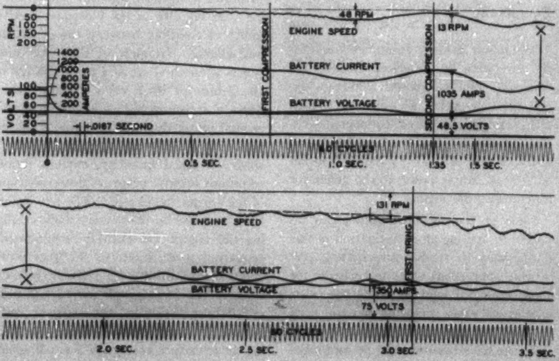
5. The governor and fuel injection system used on this engine are arranged so that a gear pump in the governor must build up a sufficient pressure and flow of oil to operate its power piston before any fuel can be injected into the engine cylinders. Observations indicate that when starting from rest after several minutes shutdown, the engine must turn over approximately three complete revolutions to obtain a fuel rack position equal to that required at idling speed and no load, which corresponds approximately to the minimum charge of fuel which the engine can fire successfully. If the engine speed at the end of three revolutions is sufficient to heat the charge of air undergoing compression to the igniting point of the fuel oil, the engine will start. If the blow-by, slowness of compression, coolness of the engine, or radiation losses are such as to prevent the rise of the combustion air up to the ignition temperature of the fuel by the time three revolutions have been made, additional time, or additional time and cranking speed, will be required before the engine can fire and run under its own power.

From the foregoing it should be clear that the observed speed at which the engine first begins to fire does not necessarily bear any relation to the minimum speed at which the engine could fire under the particular temperature conditions. When the engine does begin to fire, its speed rises at an increasing rate with a corresponding change in the rate at which the motor current decreases. This change in rate of decrease of the motor current is found to be the best indication on the oscillograph records of the particular compression stroke which resulted in the first explosion.

The three pulsations per revolution which occur in all the quantities it is desired to measure make necessary the establishment of some arbitrary method of determining their value at the time of firing. For the purpose of this investigation, the average value during the one-third revolution preceding the first explosion will be considered as the value of that quantity at firing.

The conversion of cranking-motor current as read from the battery-current trace on the oscillograms to motor torque is accomplished by reference to figure 2. This is the type of curve sheet commonly prepared to cover the cranking characteristics of a railway-type Diesel-driven generator. In the present discussion, consideration need be given only to the torque-versus-ampere curve. To determine the torque delivered to the Diesel engine at the time of firing, a correction must be made to the value read from the curve to allow for the torque developed by the motor, but which is absorbed internally in accelerating its rotor. The value of this accelerating torque is obtained by first determining the average

Figure 1. Oscillogram showing engine cranking and starting



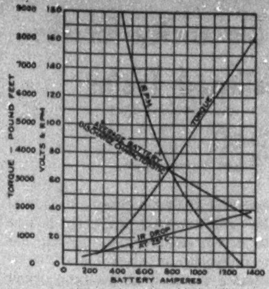


Figure 2. Engine cranking characteristics of GT-551 traction generator with 56 cells of MVA-13 Exide battery

rate of change of speed at the time of firing and applying the formula

$$T=K\left(\frac{\text{rpm}}{\text{second}}\right), \text{ where}$$

T = torque in pound feet absorbed by rotor inertia

K = a constant having a value of 12, being in the general case $WR^2\times\frac{2\pi}{60\times32.2}$

$\left(\frac{\text{rpm}}{\text{second}}\right)$ = average acceleration at time of firing expressed in revolutions per minute per second

On some of these tests this correction factor turns out to be a very appreciable percentage of the total torque developed by the starting motor.

After this discussion of some of the significant events leading up to the first explosion and a few words regarding the method of determining specific voltage, current, speed, and torque values from the ever-changing values recorded on the oscillograms, we have reached a point where the story told by figure 1 becomes much more understandable.

On this record, time progresses from left to right in the conventional manner. The lower trace is the 60-cycle timing wave, having a time of 0.0167 second between successive upward peaks. Immediately above it is the straight horizontal zero reference line of the battery-voltage element, which shows a maximum deflection corresponding to 95 volts immediately prior to the closing of the starting contactors. The horizontal line immediately above the battery-voltage zero line is the battery-current zero line. Both elements deflect upward for increasing values. However, in the case of the tachometer generator's armature voltage trace at the top of the film, the deflection has been reversed so that a downward trend indicates increased engine speed. Elapsed time measurements will all be referred to the instant that battery current starts to flow.

For convenience, a small amount of overlap has been allowed on the upper and lower portions of the oscillogram as reproduced, the reference line X-X being shown on both portions of the picture. The upper portion shows three compression strokes (one partial and two full) while the lower portion shows 11 compression strokes. Thus the entire record covers approximately $4^1/_2$ revolutions, with an elapsed time of less than four seconds.

The exact location of the peak torque point on the first partial compression stroke is not obvious from a casual inspection of the oscillogram, but may be located accurately by integrating the area between the speed trace and its zero reference line. It will be noted that, following this first compression stroke, the angular velocity of the engine momentarily reaches a value equivalent to 48 rpm, but drops back to 13 rpm at the maximum torque point of the first full compression stroke. At this instant the record shows the battery voltage to be 46.5 volts, and the current 1,035 amperes, with 1.35 seconds elapsed time. By referring to figure 2 we find 1,035 amperes corresponds to 5,450 pound-feet torque.

Having passed over the maximum torque point of the first full compression stroke, the torque required for succeeding compression strokes is, as indicated previously, materially reduced by virtue of the energy recovered from the expansion of the air previously compressed. Because of the series motor characteristics of the starting motor, the system accelerates quite rapidly, with a relatively uniform dropping off in current. A smooth curve drawn through the peaks of the current trace shows a decided break following the ninth full compression stroke. Thus it is on the ninth full compression stroke or approximately 3.1 revolutions from rest, and after 3.10 seconds elapsed time, that the first explosion took place. Although the starting contactors were held closed for approximately 0.9 second after this first explosion, they could have been opened sooner, and the engine would have continued to run under its own power, accelerating up to the idling speed for which its governor was adjusted.

Averaging the traces of the current, voltage, and speed elements for the one-third of a revolution preceding the time of firing gives values of 350 amperes, 75 volts, and 131 rpm, corresponding to the figures appearing in table I. The average current of 350 amperes corresponds to 790 pound-feet torque as read from the curve of figure 2. As previously explained, this must be corrected for the torque used in accelerating the generator armature. A line drawn to represent the "average" speed of the engine prior to firing has a slope corresponding to approximately 24 rpm per second. Applying the formula $T=12$ (rpm/second) results in a value of 290 pound-feet for the average armature accelerating torque. It is only the difference between 790 pound-feet and 290 pound feet, or 500 pound-feet of torque, that is available for cranking the engine.

Conclusions

In 1930, when this particular size Diesel engine was first being applied to railway

use, its cranking requirements were given as 4,500 pound-feet breakaway torque and 1,500 pound-feet torque at 140 rpm firing speed. An equipment designed to meet these specifications was found inadequate, and in 1931 the requirements were altered to 6,400 pound-feet breakaway torque and 1,500 pound-feet torque at 80 rpm firing speed. As a result of these tests, it seems that the cranking requirements of the engine are still understated, and that at least 7,000 pound-feet torque at standstill and at least 2,000 pound-feet torque at 80 rpm firing speed should be provided. The excellent service record of the electrical cranking equipment used on these engines during the past eight years is most certainly due in part to the leeway provided by the manufacturers over the engine builder's stated requirements. It may be of interest to compare the torque rating of this engine, which is 4,952 pound-feet, with the 7,000 pound-feet or more of cranking torque required under certain conditions.

Past practice in applying electrical starting to Diesel engines has universally been based on the assumption that the breakaway torque of the cold engine represented the maximum torque requirement. This series of tests indicates that the torque required to turn a hot Diesel engine through its first full compression stroke may exceed that necessary for all other operating conditions. While no true breakaway torque requirements of this engine were obtained, the ease with which it started on test number 7 and the accumulated service experience on a large number of similar equipments tends to confirm this new point of view. Aluminum pistons were used in the engine under test. It is to be expected that the use of cast-iron pistons might materially change starting conditions.

Electrical equipment for engine cranking could most certainly be more efficiently designed and applied if additional information on the actual starting requirements of large Diesel engines were available. Special caution must be used if an attempt is made to apply data derived from these tests to other large engines differing from it as regards number of cylinders, size of cylinders, or combustion cycle.

Discussion

Discussion will be found in the 1941 annual TRANSACTIONS volume and in the June 1941 SUPPLEMENT to ELECTRICAL ENGINEERING—TRANSACTIONS SECTION.

The Application of Electricity for the Auxiliaries of Railroad Trains

J. E. GARDNER
MEMBER AIEE

Synopsis: Although the application of electricity for the auxiliaries of railroad trains has not been as spectacular as its use for traction purposes this has increased in a remarkable manner since its first application for electric-lighting purposes about 60 years ago.[1] This application was confined largely to lighting purposes until the last few years when streamlined high-speed passenger trains and air-conditioned cars have ushered in a new era of railroad transportation. This paper points out the increased use of electricity for auxiliaries other than those in electric and Diesel-electric locomotives.

First Uses of Electricity on Cars

THE earliest applications were for lighting purposes only and were of the following systems:

First. The head end system, consisting of a steam engine generator or steam turbogenerator, together with several sets of storage battery. This furnished lights to an entire train.

Second. The axle-generator system, consisting of a generator belted to one of the car axles, combined with a storage battery. This furnished lights to the individual car on which it was applied.

Third. The straight storage system, consisting of several storage batteries on a train, the batteries being charged at terminals.

In addition to these, numerous other experiments were tried, even including a windmill-driven generator attached to the front of a steam locomotive.

Head-End System

The "first" method was called the "head end" system of lighting, so called due to the turbogenerator being located in a baggage car at the head end of the train. With the head-end system several storage batteries were distributed in the train and the nominal voltage was either 110 or 64 volts. The generator was operated at scheduled times with most of the battery charging done in the daytime to prevent excessive lamp burnouts due to overvoltage or else an adjustable resistance was used in the lamp circuit during charging periods. Cars were equipped with an overhead train line consisting usually of three 4/0 cables with two of the cables cross connected at the rear of the train in order to give more uniform lighting voltage throughout the train by means of a three-wire loop system.

In earlier head-end installations a generator of about 25-kw capacity supplied energy for electric lights and battery charging for an entire train but the advent of air conditioning has increased the electric load to such an extent that electric lighting is now only a minor part of the total electric load.

Some of the shorter Diesel-driven streamlined trains use a nominal 64-volt generator belted to the main Diesel engine but the longer trains use one or more auxiliary Diesel-engine-driven alternators which furnish 220-volt 60-cycle three-phase power for the train. This voltage was used as 220 volts has been adopted by the American railroads as the standard a-c voltage for station and coach-yard standby connections for air-conditioned cars.

However, especially where a certain amount of electric heating is used, this voltage necessitates unusually heavy train lines so that for trains of more than 10 or 12 cars a higher voltage would be more economical. The next step would be to 460-volt three-phase generators or, if much electric heating is used on the train, 2,300-volt three-phase generators would undoubtedly prove more economical.

This use of head-end power is feasible only with articulated trains or others that are operated as a unit and on account of the increased flexibility the greater number of passenger cars have their own individual axle generators and batteries. As a result the head-end system has been abandoned for other trains with the exception of certain suburban trains where the turbogenerator is located on the locomotive. The usual practice on such suburban trains is to omit the storage batter-

Paper 40-123, recommended by the AIEE committee on transportation, and presented at the AIEE summer convention, Swampscott, Mass., June 24–28, 1940. Manuscript submitted April 18, 1940; made available for preprinting May 31, 1940.

J. E. GARDNER is electrical engineer, Chicago, Burlington, and Quincy Railroad Company, Chicago, Ill.

1. For all numbered references, see list at end of paper.

ies and operate the turbogenerator whenever any lights are required in the train.

Axle Generators

For non-air-conditioned cars the axle generators have generally been of from two to four kilowatt capacity, using 32-volt batteries of from 250 to 350 ampere-hour capacity.

For air-conditioned cars axle generators, 15 and 20 kw capacity, are in common use with electromechanical air conditioning systems, with 1,000-ampere-hour batteries at 32 volts, almost the minimum size. A nominal voltage of 32 is in general use although certain roads are using 64 volts to reduce the size of cables and other current-carrying equipment.

For the smaller axle generators, such as four kilowatt, flat rubber belts have been the general standard although a number of vee belts and a few chain drives are in use. For 15- or 20-kw axle generators either gear drives or combination vee-belt and gear drives are universally used, the large majority of the generators being suspended from the body of the car and driven through splined propeller shaft. However, a number of generators are truck suspended and driven either by vee belts or spur gears.

Successful air conditioning of cars has been much more difficult than air conditioning of buildings due to the low narrow rooms, the limited space available for equipment, and the limited power supply. Much care has been used in developing air-conditioning control and air distribution in order to provide better temperature conditions and to reduce objectionable drafts.

Power Supply for Air Conditioning

Various methods are used to drive the Freon compressor when the Freon compression system of air conditioning is employed.

One system uses a d-c motor, often in the same frame with a 220-volt three-phase motor for station or yard use.

In a second system the compressor is driven from the axle through an electric slip clutch which limits the compressor to a predetermined maximum speed. Here again an electric motor is often added to take over the compressor load automatically whenever the car speed is low or the car is standing still, this motor being sometimes so controlled that it becomes a generator when the car speed reaches a certain point, thus making a separate axle generator unnecessary.

A third system uses an automatically controlled propane-gas engine for driving the compressor.

The first two of these systems of course, take power from the locomotive to operate the compressor whereas the third system does not.

Two other systems of car air conditioning are in general use, one being the steam-jet system using steam from the locomotive and the other the ice-activated system. All systems use electric motors for driving blowers and fans inside the car, the steam-jet system uses them for pumps and condenser fans, and the ice-activated system for the ice-water pump.

Use of Diesel and Propane-Gas Engines

Four cars have been equipped with individual Diesel-engine-driven alternators which furnish power for air conditioning, lighting, electric heating, etc. Here hot water from the Diesel-engine jacket water system is also used for heating, no steam heat being used. The Diesel engine and alternator are mounted on a sliding carriage so that they can be pulled out for convenient maintenance. When in normal position they are enclosed in a steel box to quiet the engine noise. The Diesel engine is operated whenever the car is in service. The engine is started and stopped by push buttons located inside of the car and generator voltage regulation is entirely automatic. The transition between car heating and car cooling is also performed automatically.

One or more cars have been equipped with a Diesel engine driving both an air-conditioning compressor and an electric generator.

A number of cars have also been equipped with an automatically controlled propane-gas engine generator set, the majority of these being on cars using a propane-gas engine for air conditioning also.

Locomotive Lighting

In contrast with the large increase in the electric load of passenger cars the electric load of modern steam locomotives is really less than it was on the earlier installations. This is due to the higher efficiency of incandescent headlight lamps over that of the arc headlights which were used at first. A 250-watt headlight is the usual size and a steam turbogenerator with a capacity of 500 to 1,000 watts at 32 volts direct current is quite generally used as the source of power supply.

The addition of train-control equipment has increased the electric load on locomotives equipped with this but this increase has been less than the decrease due to the substitution of incandescent lamps for arc lamps.

Progress in Car Equipment

The improvements that have been brought about in the art of supplying electricity for car use have been primarily to supply more reliable power and second to supply enough power in recent years to meet the ever-increasing demands.

Axle generators and their control were improved year after year as experience brought out their weak points. Moving parts of voltage regulators were counterbalanced to protect them from sudden movement of the car, flat belts and pulleys were improved to give the belts longer life and prevent excessive belt slippage in freezing weather. Vee-belt drives and gear drives were developed to give more positive driving conditions with larger power requirements. Voltage for lights and certain motors and control has been made more uniform through lamp-voltage regulators of the carbon-pile type. Thermostatic temperature regulation is now practically universal for air-conditioned cars, both for heating and cooling.

Electric lighting in cars is being constantly improved and higher intensity provided. Lighting fixtures have been improved, perhaps occasionally with more regard to artistic lighting than to furnishing the proper intensity efficiently.

Indirect lighting has been used in many cars with good results. Lenses of both the prismatic and the "bull's eye" type are being used on lighting fixtures to distribute the light properly. Night lighting has advanced from reduced-voltage dimming arrangements to the use of small auxiliary blue lights and the occasional use of under-seat aisle lights. Many coaches now have reading lights on the lower side of the bag racks, individually switched at the passengers' will. Sleeping-car berth lights have been decidedly improved recently and special attention has been given to mirror lighting in dressing rooms. Electric lamps are of course, being continually improved and today a number of special lamps are used where the type of fixture requires it.

Fluorescent-lighted cars appeared in 1939 and a number of them are now in service. The effect produced by fluorescent lighting is good as well as novel and these lamps offer a means of improving the lighting of cars due to their high efficiency. Due to the limited amount of electricity available on passenger cars it has always been more difficult to furnish good lighting on cars than it is in buildings, consequently any improved light source is welcomed by car lighting engineers. However, with the exception of the few cars equipped with a-c generators, the common use of low-voltage direct current for car lighting has complicated the use of fluorescent lamps and made their over-all efficiency lower than it would be were a-c power available. In some installations a small motor-alternator has been used to provide the a-c power and in others a number of small vibrators have been used. Now the lamp manufacturers have introduced fluorescent lamps and auxiliaries that will operate on 64 volts direct current. One or more test installations have been made and where this voltage is available it is unnecessary to convert it to alternating current.

Ten years ago 700 watts was an average electric load for a railroad coach whereas now 2,500 watts is not considered excessive for lighting in addition to an air-conditioning load of around ten kilowatts. In other words it is not unusual for a present day coach to have over 16 times the electric load of a coach ten years ago while the addition of modern dressing and smoking rooms has decreased its passenger-carrying capacity.

There have been a few installations of electric refrigeration on dining cars but their use has not been extended as refrigerators must be kept in service when the car is standing in the coach yard between trips and this involves a serious drain on the car battery. Electric drinking water coolers are however, now frequently installed.

Electric cooking equipment is used on a small scale, that is for grilles, toasters, coffee makers, etc., but so far as we are aware there has been no completely equipped dining car as the electric range and electric water heaters would have a connected load of about 87 kw and the cost of providing power for such a load is not warranted. Consequently coal in some form is still the usual fuel for cooking, with a few installations of oil and of propane gas.

Some recent dining cars however, have motor-driven blowers to furnish draft for the range and have electric dish washers and garbage grinders.

Other miscellaneous electric devices on modern cars are radios, either a-c receivers with a motor generator set or inverted rotary converter or else a-c receivers of the automotive type. In fact radios have been in common use on the western roads for over ten years and a few are in use in the east.

In a number of cases one receiving set operates loud speakers in other cars or even on an entire streamlined train and there are a number of installations of radio-phonographs.

The introduction of electric razors has caused a demand for 110-volt a-c outlets in dressing rooms. This voltage has generally been obtained by the use of vibrating inverters.

The need of improved air brakes for high-speed trains has caused the use there of electric control in connection with the air-brake system. With such control the brakes can be applied at the same instant on every car in the train. Automatic track-sanding devices and devices to prevent wheel sliding with heavy brake applications are sometimes added.

This equipment does not require much electricity for its operation but does necessitate much additional wiring and equipment on the train.

Station and Coach-Yard Facilities

Station and coach-yard requirements have naturally been greatly increased due to the increased use of electricity on cars. Battery-charging facilities at terminals have always been necessary with axle-generator cars. Formerly the capacity of such battery-charging plants was determined by the needs in adverse winter weather when batteries would become exhausted due to excessive belt slippage.

The present use on air-conditioned cars of batteries having a capacity three or more times than formerly used has changed the heavy battery-charging season to the hot summer season and in many cases has made the former facilities inadequate.

As the majority of cars air conditioned with the Freon compression system have 220-volt three-phase motors for use in terminals this has required many installations there of a-c receptacles, each with sufficient capacity to furnish power for a 15-horsepower motor. Incidentally this motor frequently operates the d-c compressor motor also as a generator to furnish sufficient direct current to carry the blower motors, electric lights, etc., on the car.

To avoid the expense of installing additional high-capacity battery-charging circuits at a terminal already equipped with a-c receptacles, portable motor generator sets or rectifiers are in quite common use. Generally these are enclosed units mounted on rubber-tired wheels so that they can be moved to the side of a car when needed. A line of small portable gas-engine-driven generators is also on the market for use where a-c power is not available.

Passengers will undoubtedly continue to demand higher intensity of electric lighting in passenger cars just as they continue to use higher intensity in their homes and offices.

Conclusion

A recent committee report of the Association of American Railroads[2] estimates the possible total load of a railroad car as follows:

Lighting, etc.	5.0 kw
Air conditioning	10.0 kw
Overhead heat	15.0 kw
Water heating	10.0 kw
Battery charging	5.0 kw
Total	45.0 kw

With steam as the common source of heating for passenger cars there is not likely to be much electric heating used, especially on cars equipped with axle generator so that the committee report is undoubtedly correct in predicting that 30 kw is undoubtedly the limit to the size of future axle generators.

A New High-Speed Thermal Wattmeter

JOHN H. MILLER
MEMBER AIEE

Synopsis: The thermal converter discussed in this paper is of the type which produces at its output terminals a millivoltage proportional to the polyphase power connected to its input terminals, the connections being made as for a wattmeter. High-speed response is secured through the use of a new circuit network wherein the thermocouples function also as heaters. Response time of the order of one-half second is obtained. The use of nickel-alloy transformer cores saturating at overloads broadens the overload capacity of the thermal unit itself. Thermal converters of this type are widely used in the summation of power.

THE measurement of various electrical quantities through the medium of heat has intrigued engineers for many years. Instruments indicating through the mechanical expansion of an electrically heated member were among the very first available to the engineer. However, difficulties in compensation for ambient temperature changes and the lack of perfectly elastic materials at the higher temperatures have caused such devices to be replaced by others not subject to such deficiencies.

The thermal ammeter, with a conventional, permanent-magnet moving-coil movement actuated by the potential developed by a thermocouple in thermal contact with the heated member, has no such inherent disadvantages and may be completely compensated against the effect of ambient temperature variations. Through the use of noble-metal alloys for heater and couple, long-time stability is assured. Such instruments are considered as standard for the measurement of current at frequencies above the conventional design range of electromagnetic devices. Mention should also be made here of thermal converters in vacuum for low currents and those having thin tubular heaters for heavy currents at the higher frequencies, all expanding the range of usefulness of the general principle. Through the use of suitable low-range thermal instruments of this type and series impedances of suitable characteristics the accurate measurement of potential becomes possible even at the higher frequencies.

Theory

The measurement of power through thermal means is nearly as old as the measurement of current. Two heated units are used, one of which is heated by the algebraic sum of two derived currents and the other, by their difference. One of the derived currents a, is in phase with and proportional to the circuit current; the other, b, is in phase with and proportional to the potential. The current in one heater is then

$$\sqrt{a^2+2ab\cos\varphi+b^2}$$

and in the other is

$$\sqrt{a^2-2ab\cos\varphi+b^2}$$

where φ is the phase angle between current and voltage. The quantity of heat produced in the two heaters, assuming the resistance to remain constant, is I^2R, or

$$R(a^2+2ab\cos\varphi+b^2)$$

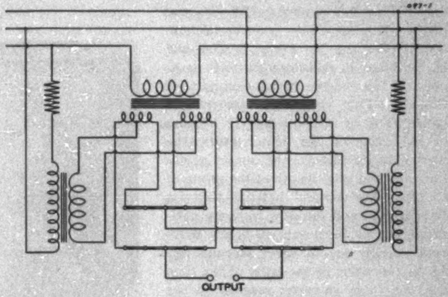
and

$$R(a^2-2ab\cos\varphi+b^2)$$

respectively. This heat is lost largely by conduction and convection with very little lost by radiation, all by reason of heater design. Goodwin,[16] shows that under such conditions, and for the relatively small temperature rise of less than 200 degrees centigrade used here, the temperature rise of the heated member is very closely proportional to the quantity of heat produced in it. If an indication can be obtained proportional to the *difference* between the temperature of the two heaters, the squared terms cancel, and an indication results proportional to $4R\,ab\cos\varphi$, or to power.

The derived currents are usually obtained through transformers. Current transformers of conventional design or modified to meet circuit requirements may be used. Potential transformers are also required to give a current in the network which is a function of the true voltage but of the same order of magnitude as the full-load current from the current transformer for optimum operation of the thermocouple heater combination. Resistance in the potential circuit may be added in the primary or secondary for adjustment and to maintain the derived current truly representative of the potential.

Figure 1. Complete schematic circuit of polyphase thermal converters



Prior Devices

The Lincoln demand meter functions on this principle, the deflection of thermally responsive bimetallic spirals associated with the two heaters and coupled in opposition giving the final indication. Another form of device disclosed by Lincoln,[15] and functioning on the difference of pressures developed in hydrostatic chambers associated with the heaters is representative of another method of securing the mechanism for indicating a temperature difference. Both of these methods are slow in response because of the relatively great thermal capacity of the systems and find their greatest field of usefulness in the art of demand metering where their inherent slow logarithmic response is useful.

The use of thermocouples thermally connected to the two heaters and con-

CURRENT TRANSFORMER SECONDARIES
OUTPUT
POTENTIAL TRANSFORMER SECONDARIES

Figure 2. Schematic diagram of transformer seconderies and thermocouples in one phase

nected in opposition to a d-c millivoltmeter was appreciated early in this development as indicated by a drawing in one of Lincoln's patents. The idea was further developed into commercial form some years ago by Perry Borden and H. S. Baker in collaboration with engineers of the Lincoln Meter Company of Canada. This converter, however, is rather slow in response largely because of the mass of the heater units, the surrounding structure, the couple insulation, and the total length of the group of couples. For demand metering this was satisfactory, and the slow response mitigated against burn-outs on heavy overloads, again due to sheer thermal lag. As an indication of the order of the time lag, one such converter reaches 90 per cent of its final deflection in 11 seconds or 99 per cent in 22 seconds, practically final deflection. It might also be noted that the internal resistance of the d-c millivolt circuit has generally been high, of the order of 35 ohms.

For polyphase power, two such systems may have their d-c millivolt outputs connected in series to give an output which is a function of true three-wire polyphase power and for three-phase four-wire service, three single-phase systems may have their output added. For totalizing power in independent systems which may or may not be in phase or, indeed, of the same frequency, the millivolt output of several polyphase converters may be added, with the input to the several units isolated by means of transformers.

The New Device

In the practical application of prior devices the slow speed of response has frequently prevented proper records or indications of phenomena acting at a moderately rapid rate. With a response time for 90 per cent of 11 seconds, only rather slow changes can be shown. Occasionally there have been requirements for much more rapid response, of the order of one or two seconds, which were simply impossible of attainment because of the inherent lag in the produced direct potential. A device with much more rapid response was, therefore, indicated as being most desirable and quite essential for the indication of material system power changes happening within a few seconds.

Another difficulty with the prior devices is their relatively high resistance. While largely used for totalizing in conjunction with potentiometer-type indicating or recording devices, in some instances simple indicating instruments are deemed suitable for the application. However, with the normal output of 50 millivolts at full rating of the prior devices, with an internal resistance of 35 ohms a maximum of only 18 microwatts could be supplied to an instrument. Even though several such units were totalized, the energy is still very small if it must be transmitted over any considerable length of line. It was indicated, therefore, that a new device should have a much lower internal resistance as respects the output circuit, and, if practicable, a higher millivolt value. As evidence that this has been accomplished, the new thermal converter produces 100 millivolts with an internal resistance in the millivolt circuit of 1.8 ohms so that 1,400 microwatts may be taken from it at full rating. This increase of about 75 to 1 in total output to the indicating or recording device, allows for the use of indicating instruments with better performance characteristics over considerable line lengths; the device will also actuate a direct-writing d-c recording instrument although not at any great distance.

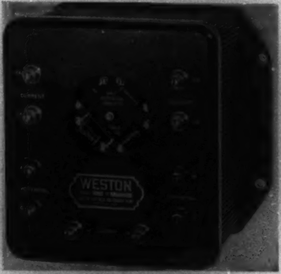

Figure 3. Assembled thermal converter with plate removed showing resistors for field adjustment

The two desirable features of more rapid response and lower resistance would seem to be possible if the thermocouples and heaters could be more closely associated to secure better heat transfer; the mass of the thermocouples might then be reduced and the resistance of the couples themselves also materially lowered.

In all of this preliminary study it was also obvious that the overload capacity was important and should not be reduced in the improved design. Disregarding for the moment the apparent inconsistency of rapid response and high overload capacity, it is obvious that for a short time constant the heaters and associated thermocouples must be made small in mass. Such heater and thermocouple assemblies as used in ammeters, with temperature compensation, would serve except for the fact that in these the couple is welded directly to the heater, and in the conventional, previously used circuits for watt converters these welds would result in cross-connected short circuits. While couples have been attached to heaters with insulation between, the assembly is usually difficult and fragile if reasonable response speed is obtained.

The Circuit

A study was therefore initiated as to the possibility of using conductively connected couples and heaters and evolving a suitable circuit network. Figure 1 shows such a circuit where the thermocouples proper also act as heaters, somewhat as in the bridge-type converters for

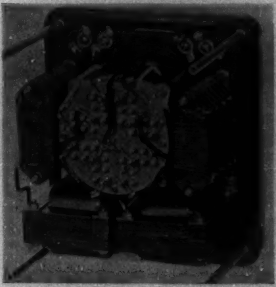

Figure 4. Interior assembly of polyphase thermal converter

thermal milliammeters. The thermocouple wires shown solid are of one material, those in outline of another alloy. The wires are of the same size and the same resistance, but their thermoelectromotive force is considerable with respect to each other. The small circles represent the studs to which the couples are attached and which function as the cold ends of the thermocouples, being bolted to a heavy brass plate with thin mica insulation. This arrangement gives excellent heat flow from the studs to the brass plate which serves as a thermal base line. The temperature rise of the thermo junctions between these studs, above the temperature of the studs and the brass plate, is a direct function of the I^2R loss in them, and without regard to the ambient temperature. And the millivoltage produced by each thermo junction is also a direct function of the I^2R loss except for the slight curvature of less than one per cent in the millivolt versus temperature relation of the materials selected and over the temperature range actually used.

For simplicity in the schematic diagrams, two couples only are shown on each side or a total of eight in all for one phase; in the final polyphase device to obtain the full 100 millivolts, a total of 40 couples are used, 20 in each phase with 5 in each of the four legs of the bridge. It should be noted that the thermally produced potentials of the several couples in each arm are truly additive since each couple is brought back to a pair of studs representing the cold ends with the center junction at a higher temperature.

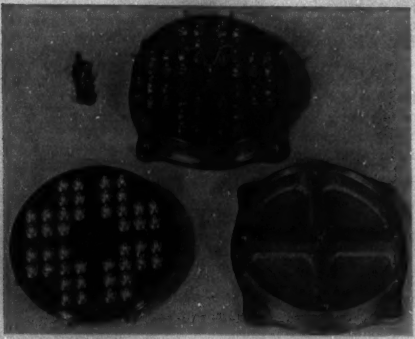

Figure 5. Details of the thermocouple group

Figure 2 shows a schematic diagram of the transformer secondaries and couples alone of one phase only, and it will be noted that the output terminals are symmetrical and at zero alternating potential with respect to each other from either transformer. The upper set of couples carries the sum of the two currents and the lower, the difference; hence, the upper set will be at a higher temperature than the lower. If the couple wires change materially in resistance, that is, have a high temperature coefficient of resistance, the current from the potential transformer will no longer be divided equally in both branches. This, however, may be largely prevented through the use of alloys having low temperature coefficients of resistance as compared with the coefficients of pure metals.

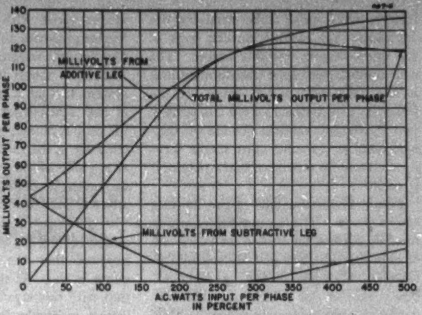

Figure 6. Total millivolts output for one phase and millivolts from additive and subtractive groups individually

Analyzing the circuit with respect to the current transformer, it will be noted that, for a given primary and secondary current, the net secondary ampere turns remain constant irrespective of the value of the current from the potential transformer. The assembly of current transformers with the two independent secondaries, each of which is center tapped, is relatively simple and introduces no difficulties.

General Description

Such an assembly, using thermocouples operating at around one ampere, has a very fast response and will actually come to 99 per cent deflection in 0.5 second. However, this fast response would make the assembly particularly vulnerable to short-time overloads when used in a power plant or in a power system for totalizing.

Recourse has, therefore, been had to the use of nickel-iron alloy cores (Hypernik, Permalloy, Mumetal), all of which have a high permeability at low densities but which saturate quite rapidly thereafter. Such materials, if used for cores in current transformers and where toroidal lamina are used without joints, will allow for the design of current transformers which are amply accurate for the purpose, both as to ratio and phase angle, from no load to full load, with a very small drop for full load at 50 per cent power factor and thereafter will saturate rapidly and give a high degree of protection against overload. This, of course, is predicated on a fixed load and a fixed frequency; the fixed load in this instance is the thermocouple converter proper, and the device can be designed for the frequency with which it will be used. The final design has been so proportioned that the current transformer will be within one-half of one per cent of the five-ampere value up to five amperes primary current, will be within two per cent at ten amperes as representative of low power factor and at higher currents will rise very slowly.

Figure 3 shows an assembled polyphase Thermoverter and figure 4 shows the interior assembly. The toroidal nickel-iron-alloy-core current transformers which are of rather small size are contained in a molded housing back of the thermocouple assembly proper. The conventional shell-type transformers seen in the lower part of the figure are the potential transformers for the two phases; just above them on each side are the conventional wire-wound mica sheets serving as the series resistance in the potential circuits.

Figure 5 shows details of the thermocouple group. The thermocouples, which function also as the heated members, are of noble-metal alloys and are soldered to the relatively heavy studs as can be noted. The chamber on which the plate is mounted contains four chambers so that the heated air in the *A*-phase summation group for example, does not circulate in the portion containing the subtraction group and raise its temperature. This construction minimizes position errors although these are still of the order of one per cent from vertical to horizontal position, and the device should be mounted in a vertical plane as calibrated.

At full load, 500 watts per phase at 115 volts, the potential losses are about 7.4 watts for 7.5 volt-amperes and 0.8 watt for 0.8 volt-ampere in each current circuit. The output is 100 millivolts from a circuit having a resistance of 1.8 ohms.

Figure 6 shows the millivolt output of a single phase plotted against per cent load as well as the individual millivolt values from the addition and subtraction groups. Note that the subtraction group gives a millivolt value going through zero and again rising, this applying only at unity power factor. At other power factors this value will not go to zero, but the total millivoltage will still be truly representative of the total power.

Field Adjustments

The four small resistance units which are normally covered by a plate serve for field adjustments. The two upper spools are in series with the potential-transformer primaries and will allow for about five per cent adjustment of total output. The lower spools form a potentiometer system so that a fixed proportion only of the total output may be taken from the output binding posts. This is of importance in the summation of the output of a group of thermal converters where the millivolt output of each must represent a definite ratio to the primary power; with different transformer ratios the output millivolts of each unit may be so adjusted that the true summation of power is had. It should be pointed out that with this arrangement the effective output resistance from the converter is increased, and summation must be by some means drawing no current as with an automatic recording potentiometer.

Accuracy

An accuracy of better than one per cent of full-load output, 100 millivolts, is had up to 125 per cent of full-load volt-amperes; up to 200 per cent full-load volt-amperes the error is less than two per cent, again in terms of the 100-millivolt output. It should be noted that the errors at the higher volt-ampere loads are not power factor errors as such but are evidence of the beginning of saturation in the current transformers. At zero power factor the output is zero and at 50 per cent power factor no discernible power factor error as such exists.

No claim is made to high precision in a device of this sort. The effort has been rather to produce a device of moderate accuracy for use in totalizing and in conjunction with switchboard instruments with ample output and inherent overload protection.

Conclusion

With a d-c millivoltmeter connected to the output of this new converter, and a conventional polyphase wattmeter in series with the converter to a rapidly varying load, it is interesting to watch the more rapid response of the d-c instrument and converter as compared to the conventional polyphase wattmeter.

The combination of rapid response and low output resistance would indicate a larger field of usefulness for the thermal watt converter.

Discussion

Discussion will be found in the 1941 annual Transactions volume and in the June 1941 Supplement to Electrical Engineering—Transactions Section.

A Comparison of the Relative Efficiency of the Schafer and Pole-Top Methods of Artificial Respiration

W. B. KOUWENHOVEN
FELLOW AIEE

D. R. HOOKER
NONMEMBER AIEE

O. R. LANGWORTHY
NONMEMBER AIEE

THE pole-top method of artificial respiration was devised by E. W. Oesterreich[1] of the Duquesne Light Company, Pittsburgh, Pa., to give prompt aid in case of electric shock occurring while men are working on poles of power lines. When a worker receives an electric shock while working on a pole minutes elapse before he can be lowered to the ground and resuscitation started by the prone-pressure method. In the field, the elapsed time is seldom less than five minutes[2] and in many cases it is considerably longer. The pole-top method of resuscitation was developed to reduce this period. Tests have shown that an operator can reach a man working alone on a pole and start squeezing his abdomen within approximately one minute.[3] If there are two men on the pole and one receives a shock the elapsed time before the first pressure is applied is much shorter. While an operator is applying the pole-top method, other members of the line crew make preparation for lowering the victim to the ground where the prone-pressure method may be applied, should it prove necessary.

The results obtained in the field with the pole-top method were excellent, and in 1939 E. W. Oesterreich[3] reported 14 successful resuscitations out of 16 applications. This is an exceptionally fine record when compared with the reports of cases where artificial respiration was not started until the victims had been lowered to the ground.

At the request of the Duquesne Light Company a comprehensive study of the pole-top method was started in the fall of 1939 at The Johns Hopkins University. This is a joint investigation in which its schools of engineering, hygiene, and medicine are co-operating.

This paper presents a report of the first stage of the investigation and deals only with a comparison of the relative amounts of air moved by the standard Schafer prone-pressure method, the modified Schafer method, and the pole-top method.

Standard Schafer Method

The prone-pressure method of resuscitation was developed by E. A. Schafer[4] in 1907 and has been used widely. In applying this method the subject is placed on his abdomen, with one arm extended and the other bent at the elbow to support the face. The operator kneels, straddling one or both of the subject's thighs, and places his hands on the small of the back. With the arms held straight, the operator swings slowly forward and brings his weight to bear upon the patient. Then the operator swings back quickly so as to remove the pressure entirely. The hands are, however, kept in position on the subject's back. The operation is repeated 12 to 15 times a minute.

Modified Schafer Method

In the modified Schafer method of artificial respiration as employed in this investigation, the "snap-off"[5] method of removing the hands from the subject's back was used. The procedure is similar in every way to that described under the standard prone-pressure method except that the operator releases the pressure suddenly by rolling the palms of his hands outward and thus causing them to slip off the subject's back to the ground.

Pole-Top Method

At the present time the recommended procedure in the pole-top method[3] is as follows:

"1. The first man to reach the victim clears the body from electrical contact permitting the body to hang from the safety strap alongside the pole if possible.

"2. The rescuer then takes a position below the victim on the pole and after placing his safety strap around the pole, proceeds to work his way up with one leg of the victim on either side of his safety strap, and with the body of the victim between himself and the pole. When the safety strap is as high on the pole as can be reached, the weight of the victim's body is taken in a straddle position on the safety strap of the operator.

"3. The mouth of the victim is cleared of foreign substances, the tongue is pulled out and the head pushed forward toward the pole.

"4. The operator then encircles the waist of the victim (under arms) placing both hands, one from each side, on the abdomen of the victim, thumbs below the lower ribs and fingers touching.

Figure 1. Pole-top method of artificial respiration

Paper 40-180, recommended by the AIEE committee on safety, and presented at the AIEE Middle Eastern District meeting, Cincinnati, Ohio, October 9–11, 1940. Manuscript submitted August 7, 1940; made available for preprinting September 13, 1940.

W. B. KOUWENHOVEN is professor of electrical engineering and dean of the school of engineering, D. R. HOOKER is in the school of hygiene, and O. R. LANGWORTHY is in the school of medicine, Johns Hopkins University, Baltimore, Md.

The authors wish to take this opportunity of thanking the Duquesne Light Company of Pittsburgh for funds for carrying on this research and the Consolidated Gas Electric Light and Power Company of Baltimore for furnishing equipment.

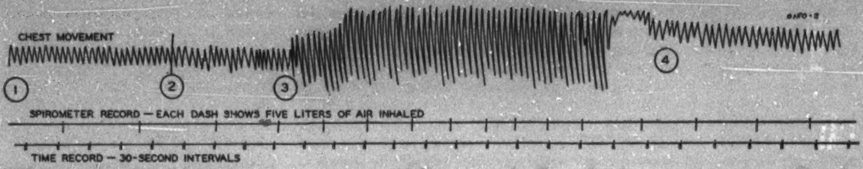

Figure 2. Record of Schafer prone-pressure test

(1) First control. (2) Second control. Operator straddling subject's thigh. (3) Artificial respiration. Note increased chest movement. (4) Final control

> "5. The operator applies a constricting action with his arms and hands, obtaining a compression force in an upward direction on the upper abdominal region. At the finish of the stroke the hands should be cupped with the fingers depressing the abdomen under the breast bone. The pressure is then released and periodically reapplied at a frequency of 12–15 per minute until the victim regains consciousness or the resuscitation is to be discontinued."

Subjects

In carrying out this investigation volunteers were chosen from among the students and the staffs of the University. The 15 men tested ranged in age from 20 to 60 years and in weight from 125 to 211 pounds. Each subject is designated by a roman numeral.

All three methods of artificial respiration were applied to each subject. Repeat readings were also made on each man. The time interval that elapsed between successive observations of the same individual varied from five days to one or more weeks.

The results reported in this paper were obtained from men who possessed the ability to relax completely and to place themselves entirely in the hands of the operator. No drugs or anaesthetics were used in the work. Every effort was made to assure the subjects and to convince them by preliminary experiments and trials that there was nothing to fear and that all that was necessary on their part was passiveness. The apparatus was so arranged that they were not cognizant of the results obtained.

Apparatus

The subject breathed through a gas mask connected with a spirometer or gas meter which measured the amount of air inhaled. Each revolution of the spirometer corresponded to five liters of air. The amplitude of movement of the chest and the rate of respiration were recorded on a smoked drum by the change or pressure set up in a pneumograph strapped around the subject's chest. Each revolution of the spirometer and a time mark at 30-second intervals were recorded simultaneously with the record of the respirations. The drum was driven by a clockwork mechanism.

Experimental Procedure

In general, the experimental procedure employed with the Schafer methods was also used in the study of the pole-top method.

In the prone-pressure tests the subject lay face down on a thin mattress which was placed on the floor. With the gas mask on and the pneumograph in place the subject rested for at least ten minutes or until his breathing was regular and normal. The smoked drum was then started and a normal record of the man's breathing taken. Then the operator took his position straddling the subject's thigh. A second or control record of the respiration was taken after a short interval in order to determine if the operator had disturbed the normal rate and amplitude of the subject's breathing. If the two records were similar, then the operator proceeded to apply the designated method of artificial respiration. A complete record of the man's respirations and of the amount of air moved was taken during the period of artificial respiration, which was never continued for more than five minutes so as not to tire the subject.[6] Following the application of artificial respiration, a third control record was taken.

A section of a standard pole approximately ten feet in length was mounted in the laboratory. This was used in the pole-top method studies. The subject was seated on a safety belt which passed around the pole. The ends of the belt were held by a special pipe support in a position which simulated an operator holding the subject. This support was developed so as to relieve the operator of the work of supporting the subject's weight during the period of relaxation and rest.

The subject seated himself on this belt, and with the gas mask and pneumograph in place, rested until his breathing became regular and normal. This usually required about ten minutes. A short record of the subject's breathing was taken, then the operator climbed the pole and took the weight of the subject on his own safety belt. The pipe support was moved out of the way. Several minutes were then allowed to pass and a second or control record of the subject's breathing was taken when respiration had again become uniform and normal. The operator then applied the pole-top method of resuscitation for from three to five minutes. A continuous record was taken on the smoked drum during this period. This

Table I. Records of Four Tests on Subject I, Pole-Top Method of Artificial Respiration

Date of Test (1940)	Operator Holding Relaxed Subject: 10 Liters of Air: Time to Move: Min.	Sec.	No. of Resp.	Rate Resp. Per Min.	C.C. Air Per Resp.	Subject Receiving Artificial Respiration: 10 Liters of Air: Time to Move: Min.	Sec.	No. of Resp.	Rate Resp Per Min.	C.C. Air Per Resp.

Av.	1	25		14.3	501	1	4		10.8	906

record was followed by a third control record while the operator still supported the subject. The operator then climbed down and the subject was again supported by the safety belt attached to the pipe support. In this position a final control record of normal breathing was taken.

A photograph of a subject on the pole with the operator in position and about to apply artificial respiration is shown in figure 1.

One of the records taken on the smoked drum is shown in figure 2. The record consists of three parts. The upper saw-toothed line is a record of the movement of the subject's chest. The increased movement during the period of artificial respiration may be seen clearly. Each dash in the middle line indicates that the subject has inhaled five liters of air. The increase in the amount of air moved during the application of artificial respiration is shown by the closer spacing of the vertical dashes. Each break in the bottom line records the passage of 30 seconds of time.

Three different individuals served as operators who gave artificial respiration during this investigation. Most of the work, however, fell to the lot of one experienced operator. The results obtained by different operators on the same subjects check remarkably well and give evidence of the uniformity of the work and of the passiveness of the subjects. Not only was the subject ignorant of the results obtained, but the operator was also in such a position as to prevent his seeing the record during the period of the application of artificial respiration.

Results

The results are given in tabular form. A small amount of resistance was introduced by the subject's breathing through the mask and the spirometer. Measurements of the variations in pressure in the mask were made with a water manomometer. They were found to amount to less than one inch of water pressure. No corrections were made for these variations nor were corrections made for changes in barometric pressure or temperature of ambient air.

VARIATIONS BETWEEN TESTS OF SAME INDIVIDUAL

As stated, two or more records were made on each individual by each of the three methods of artificial respiration studied. In table I the results for four separate records on subject I using the pole-top method are given. Two different operators were used on this subject.

The data illustrate the differences found in repeated tests on the same individual.

RATES OF RESPIRATION

In table II are given the rates of respiration with the subject relaxed and lying prone in both the standard and modified Schafer methods and with the subject relaxed and sitting on the operator's belt in the pole-top method. In addition, the rate of breathing for all three methods of artificial respiration is also given. The age and weight of each subject is included in table II.

Lying prone in a relaxed posture the average rate of respiration was practically identical for the standard and modified Schafer methods. With the subjects sitting on the operator's belt the normal rate of respiration is somewhat higher as would be expected. The average rate of application of artificial respiration was substantially the same, namely, 11 times per minute, in both of the prone-pressure methods, and at a slightly less tempo, about 10 per minute, in the pole-top method.

AIR MOVED PER RESPIRATION

Table III gives the cubic centimeters of air moved per inspiration for the subjects relaxed in the prone and sitting positions and for all three methods of artificial respiration studied. The air moved per respiration was naturally found to be the same for the two tests where the subjects were lying on the mattress. In the sitting position, it was slightly higher than for the prone position.

The artificial respiration results are given in the last three columns of table III. In the standard Schafer method the average was 868 ± 51 cubic centimeters, and in the modified Schafer method 1,028 ± 57 cubic centimeters. The pole-top method gave an average 1,363 ± 85 cubic centimeters per inhalation. The

Behavior of Point Gaps at 60 Cycles

JEAN V. LEBACQZ
ASSOCIATE AIEE

VALUES of arc-over voltages for point gaps in air have often been considered rather inconsistent and difficult to reproduce with reasonable accuracy. Accordingly, a study was made to determine, first, if certain types of electrodes might give more consistent results than others and, if so, under what conditions, and, second, whether or not it would be possible to derive a formula which would take into account disturbing factors such as humidity. The results of this study are summarized in this paper, which, the author hopes, may be a small contribution toward a better understanding of arc-over phenomena.

Equipment

The gaps tested were set up vertically in the center of a specially built cylindrical chamber, 12 feet high and 12 feet in diameter, both the floor and ceiling of the chamber being made conducting in order to minimize the disturbances from surrounding objects on the field around the gap. One electrode was grounded, the other one being connected to the high-voltage side of a 350-kv 350-kva testing transformer. The air humidity in the chamber was controlled by the introduction of water vapor.

The electrodes studied are classified as follows:

Electrode Number	Description
1	$^{9}/_{16}$-inch round rod ended by a 15-degree cone
2	$^{9}/_{16}$-inch round rod ended by a section perpendicular to its axis
3	$^{9}/_{16}$-inch round rod ended by a 90-degree cone
4	$^{9}/_{16}$-inch round rod ended by a 120-degree cone
5	$^{1}/_{2}$-inch square rod ended by a section perpendicular to its axis
6	$^{9}/_{16}$-inch round rod ended by a hemisphere
7	Loud-tone phonograph needles

All the electrodes except the phonograph needles were made of brass.

To avoid erratic results due to oxidation and burning of the electrodes, an ultrahigh-speed circuit breaker was built and placed in the circuit. The arc current was actually interrupted by this breaker the first time it went through zero after the arc started—that is, in one quarter of a cycle or approximately $^{4}/_{1,000}$ second. This eliminated almost completely the burning of the points; and the pitting of the electrodes after more than 30 spark-overs with this breaker in the circuit was much less noticeable than that corresponding to one arc-over interrupted by a five- or six-cycle circuit breaker. It is the writer's belief that, without the use of this circuit breaker, the results herein described could not have been obtained. With a conventional type of breaker, it would have been necessary to change the points after each arc-over, a very lengthy and tedious task considering that, in order to derive the conclusions found, about 6,500 values of arc-over have been observed. A brief description of this high-speed breaker is given in appendix.

Paper 40-131, recommended by the AIEE committee on instruments and measurements, and presented at the AIEE Pacific Coast convention, Los Angeles, Calif., August 27–30, 1940. Manuscript submitted May 13, 1940; made available for preprinting July 24, 1940.

JEAN V. LEBACQZ is instructor in electrical engineering, University of California, Berkeley.

The author is presenting in this paper a summary of the work he did at the H. J. Ryan high-voltage laboratory of Stanford University for his doctoral dissertation while he was a fellowship student of the Belgian-American Educational Foundation. He wishes to take this opportunity to express his appreciation to both Stanford University and the Belgian-American Educational Foundation for the facilities extended to him, and his sincere gratitude to Doctor J. S. Carroll for the aid and helpful suggestions given him.

---

plus-minus values given above are the probable error in the arithmetical mean and were calculated by the method of least squares.[7] A study of table III shows clearly that for every individual tested the amount of air moved per respiration in the pole-top method was equal or greater than that for either of the other two methods studied. The rate of respiration is, however, slightly less in the pole-top method than in the others. (See table II.)

It is also clear from the data that all three methods produce adequate ventilation of the lungs. In many of the subjects at the termination of artificial respiration there was a diminished concentration of carbon dioxide and an increased concentration of oxygen in the blood. The respiratory centers in the brain were not stimulated to activity and a brief period of apnea resulted. Soon normal breathing was resumed. This is clearly shown in the record in figure 2 where there is a brief pause in the chest movement following artificial respiration.

While in general, the modified Schafer method, where the hands are "snapped-off" the subject's back, moves more air than the standard prone-pressure method, it would, if continued for any length of time, tend to remove the skin from the subject's back.

TIME TO MOVE TEN LITERS OF AIR

A very interesting method of studying the results is to compare the time required for the subject to breathe ten liters of air. When this was done, the average times are found to be as follows:

	Minutes	Seconds
Control period—lying prone	1	22
Control period—sitting on belt	1	12
Standard Schafer method	1	2
Modified Schafer method	0	54
Pole-top method	0	43

The above comparison shows clearly that all three methods of artificial respiration studied are efficient and that the actual volume of air moved by their use in a given time is comparable to the amount that the subject would breathe under normal conditions.

Conclusion

It is evident that the ventilation of the lungs obtained by the pole-top method is adequate and that the subject receives sufficient oxygen to satisfy his needs.

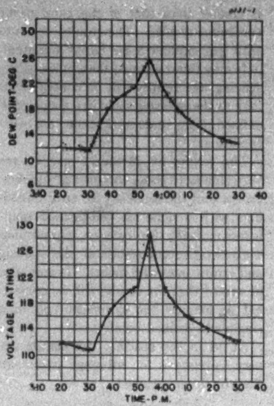

Figure 1. Variation of humidity and corresponding variation of arc-over voltage as a function of time

Gap number 3; spacing 12 inches; barometric pressure 29.9 inches of mercury

Apparatus

The voltage was measured directly from the voltmeter coil of the testing transformer. It must be noted that the purpose of this study was not to calibrate the point gaps, but to determine the relative effect of various factors on their arc-over voltages. For relative values only, the accuracy of these measurements may be considered as being better than 0.5 per cent.

The measurement of humidity required elaborate equipment. It was necessary to know, at all times, the value of absolute humidity inside the test chamber. To do this, a semiautomatic dew-point hygrometer was built according to the following principle:

Light emitted from a constant source was reflected onto a photoelectric cell by a highly polished nickel surface. If dew forms on the nickel surface, the amount of light reflected, and hence the current in the photoelectric cell, decreases. If the nickel surface is soldered on a wall of a small copper vessel, its temperature will be controllable by changing the proportions of a mixture of ice cold and hot water flowing through the vessel. This change can be achieved by the variation of current in the photoelectric cell, setting into action a suitable system of relays, motor, and valve in the hot-water circuit, to increase the temperature of the mixture as soon as dew is formed and to decrease it when dew has disappeared.

The temperature of the polished surface does not, however, respond immediately to the change of current in the photoelectric cell; to prevent any error that might occur from overshooting, a special device has been arranged to give exactly the time at which the dew forms or disappears on the polished surface. The temperature is measured by thermocouple; the polished nickel, being soldered on a sheet of copper, is used as the warm junction, the cold junction being immersed in melting ice. The resulting electromotive force is applied directly to a galvanometer, and readings are taken both when the dew forms and when it disappears, the average being taken as the true dew point. Tests made to determine the accuracy of this semiautomatic dew-point hygrometer showed that, under the most adverse conditions, the error in the dew-point temperature does not exceed 0.2 degree centigrade.

Tests and Procedure

The behavior of the following gaps has been studied:

Gap Number	Electrode Number High Voltage	Ground
1	1	1
2	2	2
3	3	3
4	4	4
5	5	5
6	6	6
7	7	7
8	5	1

Spacings ranging from 6 to 30 inches were studied, except with gap number 7, for which the maximum spacing studied was 12 inches.

All the tests were made by varying the absolute humidity from approximately 10 to 25 millimeters of mercury. The air density was practically constant during the tests. It was not possible, however, to prevent a slight increase in temperature when the humidity was increased artificially by the introduction of water vapor in the test chamber. The resulting change in air density never amounted to more than two per cent.

Since the humidity inside the test chamber was varied continuously, the dew point was recorded as a function of time, while the value of arc-over voltage was observed every 30 seconds. The results are plotted as a function of time, and the average curves drawn (sample curves are given in figure 1). From these curves, the relation between the humidity and the voltage may be easily deduced. They also make it easy to determine under what conditions the readings are erratic, and also if they must be considered as low or high compared to the average.

Results

The results obtained will now be discussed by considering: first, the influence of the shape of the electrodes on the arc-over voltage; second, the combined influence of both the shape of the electrodes and the absolute humidity on the behavior of the gap; third, the effect of humidity for each type of electrode; and, finally, some of the other factors affecting the arc-over voltage.

1. Influence of the Shape of the Electrodes

Table I gives, in kilovolts effective, the arc-over voltages observed at a humidity of 15 millimeters of mercury for the different types of electrodes studied.

It is seen that the arc-over voltage for gap number 2 is 60 per cent greater at 18 inches and 35 per cent greater at 24 inches than that of any other gap. The arc-over could not be observed at 30 inches, but it is more than 20 per cent greater than that of the other gaps (over 360 kv). With that exception, all values observed at 18, 24, and 30 inches check within less than five per cent. Since no correction has been made for air density—the influence of which may amount to one or two per cent—and since, at the same air density, variations of a few per cent may occur for the same type of gap, it may be

Table I

Spacings (Inches) Gap Number	6	12	18	24	30
1	60.1	117.5	173	236.8	298.7
2	117.5	205	283	320	
3	61.5	119.2	181.5	239.5	302.5
4	66.3	119	177.5	244.3	297
5	85	136	179.6	235.8	296.5
6	72	120	174.2	237	298
7	61.2	116.3			
8	63.8	115	173.5	229.5	293.8

stated that, at these spacings, all the gaps studied in these tests give approximately the same arc-over voltage, except gap number 2.

The results at 12 inches spacing check within four per cent for all types of electrodes except two, and may thus also be said to be identical. The two exceptions are gap number 2, with an arc-over voltage 70 per cent higher, and gap number 5, which gives results approximately 15 per cent higher, than the others.

The arc-over voltage at six inches spacing is much more influenced by the shape of the electrodes; gaps numbers 1, 3, and 7 give the same value, and as the result for gap number 8 is only 4 per cent higher it may thus still be considered the same. The other results are higher; for gap number 4 by 12 per cent; for gap number 6 by 20 per cent; for gap number 5 by 40 per cent; and for gap number 2 by 95 per cent.

These results show that, as was expected, the smaller the spacing, the greater the influence of the shape of the electrodes.

2. Erratic Nature of Point Gaps

Gap number 2 will not be considered in the following discussion, because it gives erratic results at all spacings studied, and its arc-over voltage is always much higher than that of gaps formed by the other electrodes. The results obtained for the other gaps are shown in figure 2, *a* to *e*, and explained hereafter.

At six inches spacing, gap number 1 gives consistent results when the electrodes are clean. When they are burned, however, the readings are erratic and appreciably higher than those of clean points. The same effect has been observed for the phonograph needles, where a slight burning of the tip tends to make the results erratic and to increase the average arc-over value; however, at high humidity, the readings stay consistent even with the points slightly burned. Gap number 3, when clean, gives consistent results, while gaps 4, 5, and 6 are erratic; their arc-over voltage is greater than that of the gaps giving consistent results. The results obtained with gap number 8 are fairly consistent.

It may thus be stated that, at six inches spacing, the results will be consistent as long as the electrodes end in a single well-defined point, and erratic under the other conditions.

The results at 12 inches spacing are very similar to those obtained at 6 inches, except that the tendency for erratic readings with a none-too-well-defined point is less marked; for instance, gap number 4 gives consistent results at this spacing and erratic ones at 6 inches. It may also be stated that the results will be consistent as long as the electrodes end in a single well-defined point.

At 18 inches spacing, the results are very consistent for all gaps under all the conditions studied.

Figure 2, a to e. Variation of the arc-over voltage as a function of absolute humidity for the gaps studied at the following spacings:

	15	63.8	115	173.5	229.5	293.8
	20	65.5	120.2	183.5	243.2	310.5

Note: Values in brackets have not been used for computing the relative influence of humidity.

* These values correspond to a spacing of $6^{3}/_{16}$ inches.

At 24 inches spacing, gap number 5 is the only one to give consistent results for all the conditions studied. With all the other electrodes, the results are consistent below a certain value of humidity, which will be referred to as "critical humidity". Above that value, they are always very erratic; the maximum readings fall on the extrapolated curve of voltage-humidity, but the average is notably decreased. Besides, it seems that, if the humidity is increased much farther, the voltage stays practically constant. The critical value of humidity appears to be approximately 20 millimeters of mercury for gaps numbers 1, 3, 4, and 6, and 23 millimeters of mercury for gap number 8.

The results at 30 inches spacing are entirely similar to those obtained at 24 inches; gap number 5 gives consistent results under all the conditions tested, while the others show a critical humidity, beyond which the average is decreased below the values expected from extrapolation. The critical value of humidity is approximately 17 millimeters of mercury for gaps numbers 1, 3, 4, and 6, and 20 millimeters of mercury for gap number 8.

The conclusion, therefore, is that, in order to obtain consistent results with the rod diameter used and at spacings between 6 and 18 inches, clean electrodes ending in a single well-defined point must be used. At spacings between 18 and 30 inches, however, a type of electrode offering several sharp points—such as a square rod ended by a plane section—should be used to obtain consistent results under all humidity conditions. Finally, a composite gap such as gap number 8 shows characteristics similar to those of gap number 1 at small spacings, while at large spacings, its behavior approaches that of gap number 5.

3. Influence of Humidity

For all the electrodes studied, the arc-over voltage increases linearly with the absolute humidity. There are, however, two exceptions. At six inches spacing, the arc-over voltage of the electrodes which give very erratic results does not seem to be influenced by humidity. At large spacings, when the humidity is greater than its critical value, the proportionality law holds true only if the maximum instead of the average readings are considered; and, for still higher values of humidity, the arc-over voltage seems to become independent of humidity.

Since the function of arc-over voltage versus humidity is linear, it was easy for comparison to compute the value of "relative influence of humidity". The author has called relative influence of humidity the percentage of increase in arc-over voltage corresponding to an increase of one millimeter of mercury of water-vapor pressure. It is thus given by:

$$I_h = 10\,\frac{V_{20} - V_{10}}{V_{15}} \text{ in per cent}$$

where V_{10}, V_{15}, and V_{20} are the arc-over voltages corresponding respectively to values of absolute humidity of 10, 15, and 20 millimeters of mercury. The values of I_h, obtained from tables II and III (see appendix), are plotted on figure 3, *a* and *b*.

It is seen immediately that the influence of humidity is far from being constant at all spacings. It attains a maximum of approximately 1.2 per cent per millimeter of mercury for spacings between 18 and 24 inches. On the other hand, the values observed may be considered as practically independent of the type of electrodes—with the exception of those observed with gap number 2.

4. Other Factors Affecting the Arc-Over Voltage

Some observations made showed—as had already been observed—that the point gaps arc-over voltage increases with air density. However, no systematic study of that factor was made during these tests.

Some other factors as yet unknown have a decided influence on the point gaps arc-over voltages: differences as high as three per cent were observed from one day to another—sometimes even on the same day when the air of the test chamber had been disturbed—even if the temperature, barometric pressure, and humidity were exactly the same. It is supposed that these factors are either vapors or impurities such as dust parti-

cles in the air. This assumption is based on two observations made with gap number 1, at six inches spacing. The introduction of small quantities of ether vapor in the test chamber increased the arc-over voltage by approximately 17 per cent. A noticeable increase in voltage was also observed after introduction in the test chamber of vapors from moist wood. Lack of time unfortunately prevented any systematic research along these lines.

Conclusions

The results obtained from approximately 6,500 point gaps arc-overs under varying conditions may be summarized as follows:

1. The voltage at all spacings up to 30 inches increases linearly with an increase in absolute humidity.

2. The percentage of increase in voltage per millimeter of mercury increase in water vapor pressure is not constant at all spacings:

(a). It attains a maximum value of 1.2 per cent per millimeter of mercury for spacings between 18 and 24 inches;

(b). It is practically the same for all the electrodes studied in these tests.

3. At spacings of 18 inches or more, the arc-over voltage is practically the same for all the electrodes studied, provided they are ended by a finite number of points.

4. The readings are erratic at small spacings if the electrodes do not end in a single well-defined point or if that point becomes burned, thus offering a rough surface. The average is then greater than that obtained for a clean point.

5. Except for the electrodes number 5 ($^{1}/_{2}$-inch square rod ended by a section perpendicular to its axis) the readings are erratic at large spacings for high values of humidity. The average is then smaller than would be expected by extrapolation of the results obtained at lower humidity.

6. Under all the other conditions studied, the results were very consistent.

7. It is possible, by using two different types of electrodes, to obtain a gap partaking of the advantages of each electrode of which it is made.

8. Impurities or other vapors in the air affect the arc-over voltage.

Appendix

High-Speed Circuit Breaker

The ultrahigh-speed circuit breaker used in this experiment consisted primarily of a vertical plunger-type electromagnet, bearing three separate windings. The plunger had a displacement of approximately three-eighths inch, and acted on two sets of moving contacts of the breaker. It was rigidly connected to a pair of current-carrying contacts, and, during the last one-fourth inch of its travel, it opened a pair of arcing contacts. This ensured a total gap of one-half inch, quite sufficient to break a 2,000-volt circuit under oil.

The main winding carried the total primary current of the high-voltage transformer; the second winding created a flux exactly opposed to that produced by the exciting current of the transformer flowing in the first winding; and the third winding merely acted as a hold-open device.

The main winding was so designed that the pull on the plunger averaged about 80 times the weight of the plunger during the first one-fourth cycle of the arc-over current. At the end of this one-fourth cycle, the current went through zero, since it starts on the crest of the voltage wave and is practically in phase with the voltage. At the same time, the current carrying contacts had separated about $^{3}/_{16}$ inch, and the arcing contacts were beginning to move at such a velocity that the insulation between them and the stationary contacts was building up faster than the recovery voltage, thus preventing the arc from being established.

The purpose of the second winding was to prevent any pull on the plunger that might be caused by the exciting current, the value of which was approximately $^{1}/_{30}$ of the arc-over current. Besides, it created the only flux keeping the contacts open between the interruption of the arc-over current and the establishment of the current in the third winding.

The third winding was necessary because the contacts were not designed to close the circuit and had to be kept open until the generator voltage was brought down to zero, thus preventing any rush of exciting current while the contacts were closing. A suitable system of relays was set up so that after the breaker had opened the circuit, current started flowing in the third winding, and by manual operation of a single switch, the generator voltage was brought down to zero, the breaker closed, and the transformer voltage built up to about 90 per cent of the expected arc-over value.

The operation of this breaker proved to be very satisfactory, since practically no arcing was visible, even when interrupting currents of 300 amperes rms at 2,000 volts.

The Effect of Overexciting Transformers on System Voltage Wave Shapes and Power Factor

J. W. BUTLER
MEMBER AIEE

E. B. POPE
ASSOCIATE AIEE

It is well known that the voltage and current wave shapes of transmission and distribution circuits are distorted more or less from a true fundamental-frequency sinusoid. Several years ago extensive tests were conducted, measuring the wave shapes for different types and voltages of circuits.[1] There were however no definite conclusions drawn concerning the origin or improvement of these wave distortions.

Measurements by the authors of harmonics on various systems in the country, as well as those measurements referred to, show in general that the harmonic voltages increase in magnitude as the measurements are made farther and farther from the generating stations. This indicates that probably transformer exciting currents have more effect on system wave shapes than is usually given credit.

The nontriple odd-harmonic frequency components of exciting currents of all the transformers in a system are supplied by generators, load circuits, or system capacitances. The ohmic values of the load and capacitive circuit impedances are usually many times those of the circuits which include the generating points or similar large rotating machines. Hence, practically all of the nontriple-frequency components of exciting current for transformers can be said to be supplied by the generators.

With this thought in mind one can appreciate that transformers in outlying districts may have to draw their exciting current through a great deal of impedance. Current going through impedance naturally produces voltages in accordance with Ohm's law so it can well be expected that under the proper conditions the harmonic content of these exciting currents could have a measurable effect on system wave shapes. Further, it is well known that in general, due to inadequate regulating equipment, and other reasons, certain transformers are overexcited in order to deliver the desired voltages at the load. It is, however, not so well recognized that this overexcitation greatly magnifies these system harmonics and reduces the system power factor. This reduction in power factor results in less boost in voltage than is expected with the final result being *excessive* overexcitation in certain areas, with the attendant decreased power factor, increased losses, and increased harmonic content of the voltage and current waves. It was the desire to determine more or less quantitatively what effect this overexcitation of transformers might have on system wave shape and power factor that prompted this study.

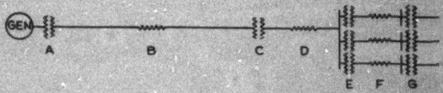

Figure 1. Diagram of the hypothetical system analyzed

Refer to table I for explanation of symbols

Experience and measurements show in general that the third-harmonic voltages and currents are relatively small. This is because nearly all three-phase transformer banks have one winding connected delta, which permits the triple-frequency currents to circulate thus preventing them from flowing beyond the first delta winding. The only triple-frequency voltage then that gets out on the system is that which represents the impedance drop in the lines to the first delta and the delta windings themselves of the third harmonic currents. Experience shows that the fifth harmonic is generally the largest single harmonic component in the current and voltage waves. It is appreciated that the magnitude of various harmonics varies considerably in any given system, but in general it has been found that the fifth is the largest component. Admittedly, in isolated cases motors or generators generate higher frequencies known as "slot ripples", which may need special attention, but this phase of the subject is not studied.

In order, therefore, to assign definite objectives to the problem, it was decided to study the effect of transformer overexcitation in a sample system on the fifth-harmonic voltage and power factor and determine what practical methods were available for improving these conditions if and when they required it.

General Method of Attack

The hypothetical system represented by figure 1 was chosen for study. Average typical circuit constants and transformer ratings were assumed as listed in table I. This circuit, with each transformer represented by its equivalent with a harmonic generator in its magnetizing branch for supplying harmonic current (refer to figure 2 and appendix) was set up on the a-c network analyzer. With this arrangement, the circuit constants, the magnitude of harmonic current flow for different values of excitation, and the ratio between substation and distribution transformer capacity could be readily varied.

With a predetermined excitation on the transformers, the magnitude of the fifth-harmonic current required was made to flow by adjusting the voltage of the harmonic generator in each transformer circuit. With these adjustments made, the fifth-harmonic voltage was then read at any desired point in the system. This procedure was carried out for normal and 110 per cent excitation on all transformers.

This type of test assumes a pure sine wave of fundamental voltage is applied to each transformer, which is not true in the strictest sense of the word since the reactance from the voltage source to each transformer results in small harmonic voltages being applied instead of a pure sine wave. This error is small for the value of voltages encountered hence the effect is neglected.

Conclusions

1. A small negligible value of fifth-harmonic voltage can be expected to appear in transmission and distribution circuits as a

[1] For all numbered references, see list at end of paper.

result of the flow of fifth-harmonic components of exciting currents required by normally excited transformers.

2. This fifth-harmonic voltage is more than doubled when the excitation on the majority of the transformers in a system is increased ten per cent.

3. The over-all system power factor can be materially reduced by exciting currents resulting from *excessive* overexcitation of the majority of the transformers.

4. Since the advantages of operating at the present established levels of meter-box voltages cannot be denied, distribution systems utilizing a large proportion of the older designs of distribution transformers requires more careful operation and regulation in order to not excessively overexcite the transformers.

5. The use of capacitors and reactors in series for the dual pupose of power-factor and wave-form improvement provides a simple, effective, and economically sound method of coping with these two problems presented by the overexcitation of transformers.

6. The replacement of obsolete distribution transformers with up-to-date built-for-the-service equipment would reduce these harmonic voltages, excessive exciting currents and losses, caused by overexcitation. This point should be more closely scrutinized by distribution engineers, particularly in view of the recent advances made in the art of building distribution transformers.[1]

7. The objectionable conditions arising from the overexcitation of transformers should further encourage the movement attempting to standardize circuit and appliance voltages so that further increases in transformer voltages will be unnecessary.

Transformer and Circuit Data of System in Figure 1

The system analyzed and represented by figure 1, does not necessarily represent any particular system in existence but it does represent in substance the equivalent amount of transformers and lines that might be used in transmitting and distributing a given block of power.

The power transformers in the line are assumed to be of 100 per cent capacity while each of the three step-down substation transformers are taken as 50 per cent capacity. Diversity in feeder loads usually requires at least this ratio of capacities. The complete circuit data including ratings and reactances of the various lines and transformers, and the per cent exciting currents used are listed in table I. For purposes of this study, it is assumed that an average normal density of 70 kilolines per square inch is representative for the distribution transformers and a density of 85 kilolines for the power transformers.

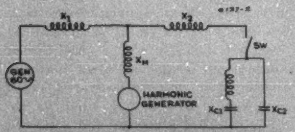

Figure 2. Diagram of equivalent transformer circuit with harmonic generator in the magnetizing branch for supplying the required harmonic currents. The switch connects a series reactor-capacitor combination for improving wave form and power factor—refer appendix

In figure 3 are plotted the data of a harmonic analysis of the exciting current of a representative iron that might be used for transformers. Thus, for the different values of excitation studied the per cent harmonic content of the exciting current can be obtained. It should be noted that these data give the per cent harmonic content of the total exciting current. Since it is the *total* amperes of harmonic current flowing that determines the voltage, these percentage values must be co-ordinated with the actual magnitudes, of exciting current. A certain transformer under an overvoltage condition might require 10 per cent total exciting current having 10 per cent fifth harmonic while another could require 4 per cent total current but having 20 per cent fifth. Thus the one having a *less percentage* of fifth may actually have *more amperes* of fifth harmonic.

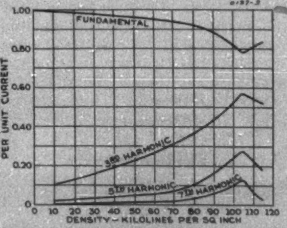

Figure 3. Harmonic analysis of the exciting current of a representative sample of iron that might be used for transformers

Data plotted as per unit of total exciting current against density

Normal Excitation on All Transformers

This study involved the determination of the fifth-harmonic voltages in the hypothetical system laid out in figure 1 for normal excitation on all transformers. This is indeed somewhat of a hypothetical condition, since never would a system be found that had normal voltage applied to all transformers. However it does have the academic value of showing to what extent normal-excitation exciting currents would generate harmonic voltages in such a system.

The voltages that the prescribed values of harmonic current caused to appear in the test system are shown plotted by the solid lines in figure 4. Curve *A* represents the conditions when the ratio of distribution to substation capacity is unity. Here it is seen that the fifth-harmonic voltage gradually rises from zero at the generator to approximately 0.02 per unit in the distribution area. The solid curves labeled *B* and *C* show the voltages when the distribution-transformer capacity ratio was increased to 2 and 3 respectively. Here it is seen that the harmonic voltage increases slightly for these two conditions. These figures are representative of the lower values of fifth-harmonic voltages measured in actual systems.

1.1 Per Unit Excitation on All Transformers

The next consideration was that of determining the fifth-harmonic voltages when all the system transformers were overexcited ten per cent. Again, the reader is cautioned that this does not necessarily represent a practical case, but it does show, when compared with the results of the previous case how the harmonic voltages can be expected to increase when the transformers are operated above their normal densities.

The exciting currents for this condition of excitation, for the two types of transformers are listed in table I.

Cases *A*, *B*, and *C* were analyzed for this condition just as they were for normal excitation. The dashed curves in figure 4 show the fifth-harmonic voltages measured for the three different values of distribution transformer capacity. These data show that the harmonic voltages are more than doubled over the values obtained for the condition of normal excitations on all transformers.

In an actual system, these harmonic voltages are usually amplified more or less by the transmission line and transformer capacitances, so it is not uncommon to find voltages much higher than those shown in figure 4. Also, the magnetizing current required by induction motors and other "iron core" loads have their effect in increasing these voltages. In fact all loads with nonlinear impedance characteristics contribute to this phenomenon.

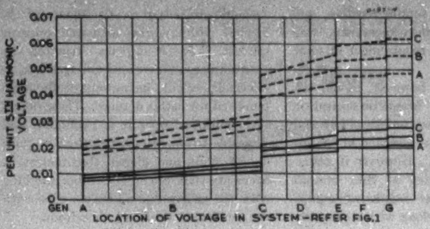

Figure 4. Magnitude of fifth harmonic voltage appearing in the hypothetical system studied

Solid curves—Normal excitation on all transformers

Dashed curves—1.1 per unit excitation on all transformers

Curves	A	B	C
Ratio of Distribution Substation Capacity	1	2	3

The authors have studied test data taken on two systems that exhibited unusually high fifth-harmonic voltages. In these tests it was found that a general lowering of the voltage levels by approximately 10 per cent, resulted in a decrease of 50 per cent in the fifth-harmonic voltages.

On another occasion, severe overcurrents were being experienced due to the circuit being in *partial* resonance with capacitance. It was found that a decrease of only 4 per cent in the voltage feeding the affected area reduced the harmonic condition sufficiently to cure the difficulty.

Reduction of Harmonic Voltages Arising From Exciting Currents

In certain areas the application of shunt capacitors has been somewhat impeded due to these harmonic voltages. Resonance has occurred on occasion resulting in excessive fuse blowing. Also an occasional case of low-frequency induction in communication circuits has been experienced. Almost without exception these cases have been controlled by the fifth-harmonic or 300-cycle component. Therefore it is believed that if a method of reducing this component to a negligible amount was realized, the broad problem could be considered solved.

Use of Capacitors. Since capacitors have more or less exposed this harmonic condition in modern distribution circuits during the last few years, it seems paradoxical that they could be used to suppress these harmonic voltages. Such a method however is available and attention is directed to it in this paper since it is believed to be not very well known in this country. It has however been used successfully for several years in Japan[3] in the larger capacitor installations.

The scheme consists of putting a reactor in series with a group of capacitors. This reactor is proportioned in respect to the capacitors, so that the combination is in or near resonance with the fifth harmonic. The fifth-harmonic voltage is then effectively short-circuited at the point of application with the improvised resonant shunt. In fact it can be shown that it is reduced to a negligible amount in the surrounding area for a considerable radius. The amount of harmonic current that flows into this "harmonic short circuit" is equal to the voltage at that point before the equipment was applied divided by the system impedance viewed from that point. In general this current will not be so much since the harmonic voltage isn't large to begin with and further the system reactance is large, being increased by the order of the harmonic. It is interesting to reflect on the possibilities of this scheme when carried to a limit. If a sufficient number of these "harmonic short circuits" or resonant shunts were applied to a system, practically all of the fifth-harmonic current could be made to flow in short localized paths from the transformers to the shunts, thus practically eliminating the harmonic voltages from appearing, as described in the body of the paper.

A very important point to remember in this respect is that the normal, 60-cycle power-factor improvement afforded by the capacitors is not reduced by this series reactor. Since approximately a four per cent reactor is required for this application, the 60-cycle voltage on the capacitors is raised by this amount and the net available corrective kilovolt-amperes to the system is likewise increased by four per cent. If it is desirable from other considerations to practically eliminate the flow of harmonic current instead of the harmonic voltage, the reactor can be so proportioned to make a harmonic wave trap (equation 5 in appendix) out of the capacitor bank, and as before the normal 60-cycle correction afforded by the capacitors is increased by the reactor. Thus it is seen that power-factor and waveform improvements can be obtained simultaneously by a single master stroke.

Reduction of Transformer Excitations

Reducing excessive overexcitations and providing the proper regulating equipment for voltage control would, of course, be in order where it could be justified. No doubt there are many transmission and substation transformers that could be operated at much lower densities if the distribution circuits were properly regulated.

The distribution transformers however, in general, cannot have their voltages reduced without accepting certain losses in revenue and a reduction in the quality of service rendered. As described in more detail below under power factor, it is well known that in the last several years the transformer secondary voltages have been creeping up from 110 to 125 volts and even higher. Obviously many older-type transformers originally designed for 110 volts are now operating 10 per cent and even 15 per cent overexcited. In view of these trends, it is believed that a policy of more closely scrutinizing the replacement of obsolete equipment with up-to-date designed-for-the-service apparatus would prove a sound investment.

Table I

Equipment Identification Refer Figure 1	Type of Equipment	Per Unit Rating	Per Unit Reactance on Own Base	Per Unit Exciting Current on Own Base: Normal Excitation	Per Unit Exciting Current on Own Base: 1.1 Per Unit Excitation
Generator	Sine-wave voltage source	Infinite	0		
A	Transformer—step up	1.0	0.08	0.045	0.08
B	High-voltage transmission line	1.0	0.05		
C	Transformer—step down	1.0	0.08	0.045	0.08
D	Medium voltage distribution	1.0	0.05		
E	Three substation transformers	0.5 ea.	0.05 ea.	0.04	0.07
F	Three lines—four-kv feeders	0.5 ea.	0.05 ea.		
G	Transformer equivalent of total connected distribution transformers, Case *A*	0.5	0.025	0.02	0.03
	Case *B*	1.0	0.025	0.02	0.03
	Case *C*	1.5	0.025	0.02	0.03

Cases *A*, *B*, and *C* differ only in the ratio of connected distribution to substation transformer capacity, of which the ratios are 1, 2, and 3, respectively.

SYSTEM POWER FACTOR AND OVEREXCITATION OF TRANSFORMERS

The past several years has seen in general a marked decrease in over-all system power factor. The deleterious effects of poor power factors coupled with increased loads upon system capacity and voltage are well known. The answer to the questions inquiring into the cause of this decrease in power factor has generally been "motorized appliances, air conditioning, gaseous-tube lighting, etc." These factors beyond a doubt have had their effect, but it is interesting to speculate on the effect of transformer magnetizing currents, especially when the transformers are overexcited.

Not so long ago it was the practice to serve a customer with 110 volts, or its equivalent at a higher level. Later the standard was considered to be 115, so taps were changed and general levels raised to accommodate this change in philosophy. During the last few years this meter-box voltage has risen to 120 which represents approximately a ten per cent increase over the original 110. In fact in many places it is necessary to hold 125 volts or even higher at the transformer in order that the load be served at rated voltage. During the evolution of this practice of gradually raising the voltage, new transformers designed for the voltage were of course being added to accommodate load growth, but, most of the older equipment obviously remained on the system. Thousands of kilovolt-amperes of transformers on most systems today that were built to operate at a normal density corresponding to 110 or 115 volts, are actually being operated at or above 120 volts. Transformers in general can stand this duty because they are designed for it, but obviously they must draw larger magnetizing currents to accommodate the increased flux requirements.

The effect on the magnitude of the total exciting current required by all the transformers in the circuit of figure 1 due to overexciting the transformers ten per cent is clearly seen by the figures in table II. Here it is seen that the exciting-current requirements are practically doubled, for the overexcited condition. For the case at hand, reactive kilovolt-amperes approximating 40 per cent of the system rating may be required merely to excite the transformers. These figures may of course be off a little quantitatively, but they are believed to be sufficiently accurate qualitatively to show that system power factor can be materially reduced by operating transformers above their normal densities. It is well known that many times a generator must be kept on the line merely to supply reactive, and the overexcited transformers may well be the cause of the requirement in some cases.

The transformer, however, should not be indicted for this. Magnetic saturation is a fundamental characteristic of iron and must be more or less accepted in the interests of economy. However if transformers were operated at their normal densities and proper regulating equipment were applied along with a properly designed distribution system, these exigencies would not arise. Admittedly this is a Utopia impossible to attain, but it is believed that with these facts known and understood, more attention to the problem can be intelligently and profitably applied. Magnetic saturation and magnetizing reactive kilovolt-amperes is something with which the engineer must live—hence it behooves him to treat it with respect and design his systems accordingly. It is believed that the replacement of lots of these older, overexcited distribution transformers with up-to-date designs and/or the use of appropriate regulating equipment could be justified from the standpoint of decreased losses and decreased magnetizing currents alone. One should not conclude from this discussion that power-factor improvement be attained by reducing voltages, but the over-all condition can be greatly improved by properly regulating the voltage. In this respect the authors are acquainted with one distribution system in which voltage regulators were systematically applied and much to the surprise of the engineer, the power factor coincidentally was improved from 70 to 85 per cent.

Table II

Total Per Unit Exciting Current Required by Transformers in Circuit of Figure 1 for Various Excitations and Ratios of Distribution to Substation Transformer Capacity. Kilovolt-Ampere Base = 1.0

Capacity ratio	1/1	2/1	3/1
Normal excitation	0.18	0.21	0.24
1.1 per unit excitation	0.31	0.35	0.40

Reference to the preceding section on reduction of harmonic voltages should be made for further discussion of reactive control. In this section the use of capacitors is described for improving wave form distortions due to saturation and at the same time provide leading kilovolt-amperes for power-factor improvement. It is interesting at this point to note that since shunt capacitors increase their kilovolt-ampere output as the square of the applied voltage, the increased exciting current kilovolt-amperes required by transformers at increased voltages can, to a certain extent, be automatically compensated for in this manner. These points are mentioned since it is profitable and desirable to operate distribution systems at 120 volts and higher, thus making it necessary that the engineer be provided with the proper equipment to cope with the conditions resulting therefrom.

Appendix. Use of an Equivalent Circuit for Determining Flow of Harmonic Magnetizing Currents

Consider the circuit shown in figure 2 which is the equivalent diagram of a transformer connected to a pure sine-wave voltage source with a harmonic generator in the magnetizing branch for furnishing the harmonic magnetizing currents. The circuit connected by the switch represents a set of capacitors, x_{c1}, in series with a reactor x_s and a set of capacitors, x_{c2}, with no reactor.

Consider the switch open, and the transformer excited from the pure 60-cycle source. Since there is magnetic saturation in the x_m branch, certain harmonic currents will flow and these can be represented as being driven through the system by a harmonic generator located in the x_m branch. Then letting

i_n = harmonic current
x_1 = 60-cycle reactance of system up to transformer plus transformer primary reactance
x_2 = same on secondary side
n = order of harmonic

the harmonic voltage at the switch can be written as

$$e_n = i_n n x_1 \tag{1}$$

This reasoning assumes that the magnitude of i_n is determined solely by the applied 60-cycle excitation sine wave of voltage and neglects the infinitesimal amount that flows due to the appearance of a small harmonic voltage at the transformer terminals.

Assume further that the reactor x_s and the capacitor x_{c1} are proportioned so that

$$n x_s = x_{c1}/n \tag{2}$$

then the harmonic current meets zero impedance when the switch is closed.

Closing the switch results in the flow of i_n' through the switch of the magnitude

$$i_n' = i_n \frac{n x_1}{n(x_1 + x_2)} \tag{3}$$

and substituting equation 1

$$i_n' = \frac{e_n}{n(x_1 + x_2)} \tag{4}$$

Thus, to determine the readjustment of the flow of the harmonic current due to a resonant shunt or a "harmonic short circuit" it is merely necessary to divide the voltage at the point of application by the

Testing of Elevator Buffers by Electrical Means

E. E. KIMBERLY
ASSOCIATE AIEE

THE purpose of an elevator buffer is to stop the elevator in event it reaches the bottom of its hoistway out of control. To prevent injury to its occupants, the rate of stopping must not exceed $2^1/_2$ times gravity or about 80 feet per second per second for more than $^1/_{25}$ second. The tests on a buffer should be such that the velocity at which the elevator strikes the buffer and the rate of deceleration at every point in the piston stroke may be determined. If the buffer contains oil, it is important for the designer to know also the oil pressure at every point in the stroke.

Methods Formerly Used

The test method found most satisfactory up to this time employs a platen, driven directly from the buffer piston or by the elevator, on which a tuning-fork-driven stylus records the distance traveled by the platen during successive cycles of the fork vibrations. From this record the velocity and deceleration are calculated. A modified steam-engine type of pressure indicator operates another stylus on the same platen to record the varying oil pressure.

In methods previously used, the tuning fork vibrates with constant frequency while the platen velocity varies with that of the car. This arrangement produces a record on which the highest velocity of fall produces the fewest cycles per inch on the record. With the electrical method described, the highest velocity of fall is recorded with the greatest number of cycles per inch of record and the accuracy of the calculations of retardation are best therefore when the velocity of fall is highest. Inasmuch as dangerous deceleration rates are more likely to occur early rather than late in the stroke of a buffer reasonably well designed, it is better to achieve accuracy of measurement at the higher rather than at the lower velocities.

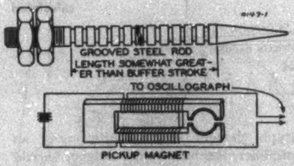

Figure 1. Pickup magnet and grooved iron inductor rod

Determination of Velocity and Deceleration

To determine the striking velocity of the elevator car, a magnetic pickup coil and grooved iron rod shown in figure 1, is used. The rod is mounted vertically on the car, attached by its upper end so that as it falls with the car it passes through the bore of the pickup magnet which is mounted on one of the guide rails. The magnet has an exciting winding of about 200 turns of number 18 magnet wire and also a secondary coil of about the same number of turns which is connected to a high-sensitivity galvanometer element of an oscillograph. As the rod drops through the bore of the pickup magnet, the changes in permeance of its magnetic circuit, caused by the grooves in the rod, vary the magnetic flux and induce in the secondary coil an alternating voltage, which is recorded by the oscillograph. One six-volt storage battery serves to excite the pickup magnet. A similar rod and pickup coil may also be used on the buffer piston itself if the performance of the piston must be known.

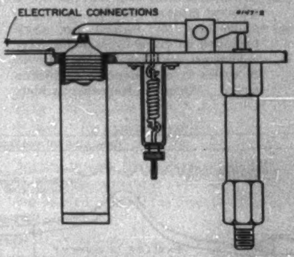

Figure 2. Carbon-pile oil-pressure gauge

A 60-cycle voltage wave on the same oscillogram as the varying-frequency alternating voltages of the pickup coils is of convenience in timing.

In calculating the velocity of the car at any point in its fall the following formula may be used:

$$V=\frac{5NL\times m_{60}}{m_r}$$

in which

V = velocity of fall in feet per second
N = number of cycles scaled on pickup record on oscillogram

Paper 40-147, recommended by the AIEE committee on instruments and measurements, and presented at the AIEE Middle Eastern District meeting, Cincinnati, Ohio, October 9–11, 1940. Manuscript submitted February 25, 1938; made available for preprinting August 23, 1940.

---

driving point impedance of the circuit viewed from that point. This fundamental principle has been used for years by engineers in making short-circuit calculations. It can be shown, within the assumptions, that this method of calculating the flow of short-circuited harmonic current in a complicated network, is correct. The demonstration above for a simple circuit is given in the interests of clarity.

It is interesting to note that if x_s is proportioned so that

$$nx_s=x_{c1}/n+x_{c3}/n \tag{5}$$

a wave trap is formed by the network, which presents infinite (neglecting losses) impedance to the harmonic thus preventing the flow of harmonic current.

Either of these reactor schemes can be used in capacitor applications depending upon the objective. The condition imposed by equation 2 reduces the line harmonic voltage to zero whereas the conditions represented by equation 5 reduces the line harmonic current to zero.

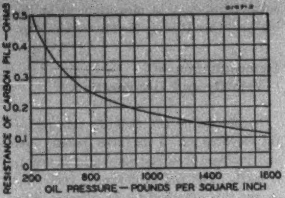

Figure 3. Typical carbon-pile pressure calibration curve

L = distance in inches between centers of adjacent grooves on rod

m_{60} = millimeters (or inches) per cycle measured on the 60-cycle timing wave

m_r = millimeters (or inches) measured over N cycles at chosen point on pickup record. When the frequency is high, three or four cycles should be used. When the frequency is low, two cycles are sufficient.

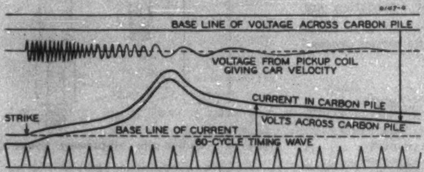

Figure 4. Typical oscillogram from which the performance of the buffer is calculated

To obtain the curve of deceleration versus inches of stroke it is necessary to plot a curve of velocity versus time from figure 5. The slope of this curve at any point is then the rate of change of velocity from which the curve of deceleration of figure 5 is plotted.

Measurement of Oil Pressure

The oil-pressure gauge consists of an oil-pressure cylinder and a carbon pile mounted together with a rocking beam connecting them as in figure 2. The carbon pile consists of 42 carbon disks each of which is $^1/_8$ inch thick and $1^1/_2$ inches in diameter. The disks were ground to a true surface on each side as far as possible. The disk pile is enclosed in a paper tube and inserted in a brass tube shown in figure 2. The rocking beam by which the pressure at the piston is transmitted to the carbon pile has a lever arm ratio of $1^1/_2$ inches to $4^1/_2$ inches. Because the long end of the beam moves only $^1/_{16}$ inch with the greatest oil pressure encountered, inertia effects are reduced to a satisfactory minimum.

The carbon pile is calibrated in resistance versus pressure. The current through the carbon pile and the voltage across it are both recorded on the oscillograph film so that the resistance may be calculated and the pressure determined for any point in the piston stroke. A calibration curve is shown in figure 3. Figure 4 shows a sketch of a typical oscillogram. Figure 5 shows the final curves of performance of the buffer.

Difficulties to Be Avoided

To obtain sufficient voltage in the pickup magnet coil to operate the oscillograph element without interposing an amplifier, the hole in the magnet should not exceed three-fourths inch in diameter when a five-eighths-inch grooved rod is used. Grooves one-eighth inch long, one-eighth inch deep and spaced three eighths inch apart were found quite satisfactory.

If there is no guide provided for the suspended rod, the impact of the car on the buffer piston may cause the rod to deflect and strike the pickup magnet instead of its hole. A long brass point fitted to the rod attached to the car proved helpful in guiding that rod through the pickup magnet in its fall. A fiber bushing in the pickup magnet hold (not shown in figure 1) was found helpful in guiding the rod. It was also found advisable to mount the magnet so that it was free to move laterally to follow any swinging of the rod.

In comparison with electric strain gauges recently developed the carbon pile has the advantage of requiring no amplifier or source of high-frequency voltage for oscillographic recording.

Summary

The curves of figure 5 are typical of those obtainable by the electrical apparatus described. Inasmuch as the oil-pressure indicator was connected to the bottom of the buffer cylinder, there was a short time interval between the instant of maximum pressure as shown on the pressure gauge and the maximum deceleration. This time interval is that required for the high-pressure wave to travel through the oil from the piston to the gauge. This difference in time demonstrates the elasticity of the light transformer oil used.

The accuracy of this method is satisfactory for all existing test codes.

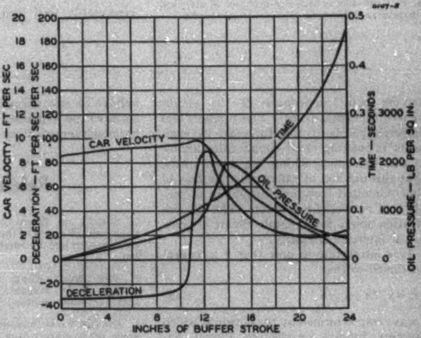

Figure 5. Typical performance curves of a buffer with poor workmanship or of poor design

Single-Phase Induction-Motor Performance Calculation

F. S. HIMEBROOK
MEMBER AIEE

IN the manufacture of electrical machines it is always desirable to calculate the performance of a machine before its construction to determine whether or not it will meet the specifications. The usual methods of predetermining performance involve the use of either a circle diagram or an equivalent circuit and since either of these methods involves considerable work there are always possibilities that errors may be introduced by slight mistakes in construction, measuring, etc. It was believed that if a method could be developed by which the quantities necessary for performance calculation could be given in the form of a set of curves considerable time might be saved provided that the accuracy so obtained was of the same degree as that given by other methods.

This paper describes the development of a method which may be used to plot, as families of curves, the quantities necessary for the performance calculation of single-phase induction motors. Consideration is first given to a circle diagram which is known to give accurate results when used to calculate the performance of motors of this type. It is then shown that all of the quantities involved in the calculation of performance are dependent upon certain ratios of the fundamental motor constants and not upon the absolute values of the constants. This means that it is not necessary to draw a new circle diagram for each motor and any diagram may be used in any number of cases as long as the fundamental relations are held constant. Thus if a number of diagrams are made for different ratios of motor constants the data required for performance determination may be evaluated and plotted in the form of curves which may be used to take the place of the circle diagrams. Such curves are at least as accurate as the diagrams they replace because slight errors in reading values become apparent when plotted and tend to be either minimized or averaged out.

Besides the motor characteristics in the usual operating range it is always desirable to know the value of the maximum torque. It was found that the information required for the calculation of the maximum torque might be determined by making use of the diagrams previously described and a method of plotting the necessary quantities in the form of curves is given.

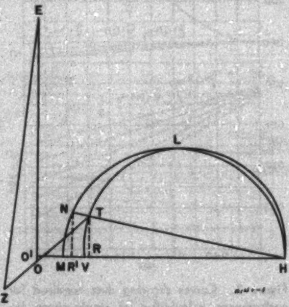

Figure 1. Circle diagram used in determining performance of single-phase induction motors

Extension of the methods given for the calculation of the performance of polyphase motors is shown to be possible and is discussed briefly.

The Circle Diagram

The circle diagram used (figure 1) is the one given by Branson[1] in his paper which explains the operation of the single-phase motor by the cross-field theory. The methods of constructing this diagram and of using it are included in appendices I and II.

By reference to appendix I it will be seen that since $O'H$ is a constant and since $O'M$ is a variable dependent only upon K_r (defined in appendix I), that the value of MH and the semicircle $MNLH$ are also functions of only K_r. Thus, for any particular value of K_r this part of the diagram is fixed.

In a like manner, the value of MV is determined by the value of K_r and point V located accordingly. The value of LH is dependent upon both K_r and the ratio r_2/X but for any particular values of these two quantities the point L is definitely located. Because points V, L, and H are all located and because all three points must lie on the circumference of one circle the center of this circle is located at the intersection of the perpendicular bisectors of lines VL and LH. After the center has been located arc VLH may be swung.

Actually the line OO' is not constant, as assumed in appendix I, but varies with the motor under consideration. However the assumed value is sufficiently close to the average value calculated for normal motors that the error introduced by this assumption is very slight. Having located point O the directions of lines OT are defined.

By definition

$$OZ = (S_1 r_1 / S_s) \times OT \qquad (1)$$

and by substituting equivalent values for S_1 and S_s we may change this to the form

$$OZ = \frac{(E/10X)}{(E/OE)} \times r_1 \times OT = \frac{(OE=10)}{10X} \times r_1 \times OT = \frac{r_1}{X} \times OT \qquad (2)$$

giving a solution for the length OZ which is a direct function of r_1/X.

Thus it is seen that the entire diagram is dependent only upon K_r, r_2/X and r_1/X and that the performance of all motors having the same values for these quantities will be identical. Since this is true it is evident that with the use of only a relatively small number of diagrams it is possible to determine the performance of a wide variety of motors. We may also proceed one step farther and plot the values of OT, MT, etc., in the form of curves and so have all of the information required for performance calculation in a convenient form. In carrying out this work for a given value of K_r it will be found convenient to plot the values of OT, MT, etc., against the length of MN since this value remains constant for a given value of K_r regardless of the ratios r_1/X and r_2/X.

This method of plotting the curves may be seen by reference to figures 2 and 3. In some cases all of the values for the

Paper 40-141, recommended by the AIEE committee on electrical machinery, and presented at the AIEE Middle Eastern District meeting, Cincinnati, Ohio, October 9–11, 1940. Manuscript submitted July 13, 1937; made available for preprinting August 12, 1940.

F. S. HIMEBROOK is electrical engineer in charge of laboratories, Master Electric Company, Dayton, Ohio.

The writer wishes to thank The Hoover Company for permission to publish this paper, the material for which was developed while a member of their engineering department.

[1] For all numbered references, see list at end of paper.

ranges of r_2/X considered do not differ appreciably and so only one value has been shown. For example the values of *TR* as shown all lie within about 0.01 inch of the value shown and since errors in measurement might have been at least ±0.01 inch it was not believed necessary to attempt to show any more than one curve.

In calculating the performance the procedure followed is that outlined in appendix II.

Performance Calculation Using Curves

In the final analysis the utility of a method lies in the accuracy of the results obtained. The performance of a one-fourth-horsepower single-phase induction motor was calculated by the use of the curves described herein and the methods described in appendix II, and is shown with the actual test data for this motor in table I. Examination of this table shows that the calculated and measured results do not differ widely in any respect.

Determination of Maximum Torque

It was known that the point corresponding to maximum torque lay on arc *VTL* (figure 1) somewhere beyond, but near to, the center of arc *VTL*. To locate this point precisely would have required the choosing of several points, calculating the data for each point, and then finding the desired point by the process of elimination. It was found, experimentally, that the point corresponding to the maximum torque lay almost midway between the center of arc *VTL* and the point of tangency between the arc *VTL* and a line drawn parallel to *ML*. The point found in this manner located the point of maximum torque closely enough for all practical purposes.

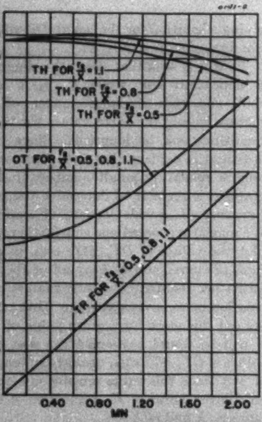

Figure 2. Curves showing data required for performance calculation of single-phase induction motors. (K_r = 0.93)

The values of *OT*, *MT*, etc., corresponding to the point of maximum torque may also be read and plotted in the form of curves. It was found convenient to plot these values against K_r as shown in figures 4 to 7, inclusive.

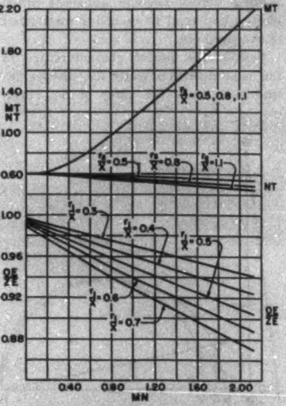

Figure 3. Curves showing data required for performance calculation of single-phase induction motors. (K_r = 0.93)

The locus of the current vector in an ideal motor follows a circular path but this ideal is deviated from in the case of an actual motor. Usually the circular locus is accurate for points in the normal operating range but some deviation is often noted when calculating the maximum torque. It has been found[1] that the maximum torque as obtained by a brake test is only about 0.92 of the calculated value and so it is necessary to multiply the calculated torque by 0.92 to secure the value to be expected in an actual motor. Aside from this, calculation of the maximum torque is carried out in the same way as for any other point. (See appendix II.)

When the calculation was made upon the motor previously considered the indicated maximum torque was found to check closely (see table I) with the measured value.

Extension of Method to Polyphase Motors

The same diagram may be used to derive a similar set of curves for polyphase motors. For this work *MH* is again equal to $10K_r$ and the length *OO′* becomes 0.05 inch for all practical purposes. The inner circle *VTLH* does not exist and point *T* lies on *MNLH*. For use with polyphase motors the values of *OT*, *MT*, *TR*, *OZ*, and *ZE* are required. These correspond to *ON*, *MN*, *NR′*, *OZ*, and *ZE* of the single-phase diagram (figure 1).

Thus without a great deal of additional work a set of polyphase curves might be obtained. However, these curves are not believed to be in as usable a form as the "*a-b-c*" curves described by Branson.[2]

Discussion

It was assumed, in deriving the material contained herein, that the core loss *OO′* could be given as 0.10 inch in all work and that the ratio of the saturation factors in the main and cross fields was unity. Some such assumption was required or a complete set of curves would have been required for each value of core loss and each ratio of saturation factors. A number of tests were computed and indicated that these assumptions might readily be made. In all use to date these assumptions have been found sufficiently accurate to warrant their use.

The ranges of values of K_r, r_1/X, and r_2/X shown in the sample curves are believed great enough to cover most ordinary motors. As special cases are encountered their data may be recorded and used to build up a more extensive set of curves.

Table I. Comparison of Measured and Calculated Characteristics of a One-Fourth-Horsepower Single-Phase Induction Motor

Quantity	Measured	Calculated
r_1	1.29 ohms	1.30 ohms
r_2	2.51 ohms	2.41 ohms
X	3.60 ohms	3.60 ohms
X_0	51.2 ohms	50.2 ohms
K_r	0.929	0.932
Full-load speed	1,747 rpm	1,737 rpm
Full-load current	4.82 amp	4.81 amp
Full-load efficiency	64.3 per cent	61.5 per cent
Full-load power factor	56.7 per cent	57.2 per cent
Full-load input	292 watts	302 watts
Maximum torque—in per centrated load torque	310	304

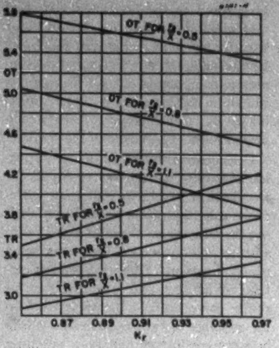

Figure 4

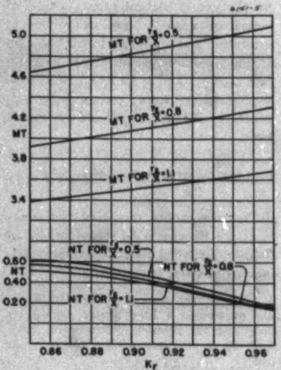

Figure 5

The results obtained by the use of the curves indicate that when the original work is carefully carried out that considerable time may be saved and results are obtained which are as accurate as might usually be obtained by the construction of a special diagram for each motor. In addition, when the curves are plotted any but the most trivial errors are immediately made evident because any errors (except consistent errors) are shown by irregularities in plotting.

Appendix I

Construction of Circle Diagram

Before constructing the circle diagram (figure 1) it is necessary to know the values of the following quantities:

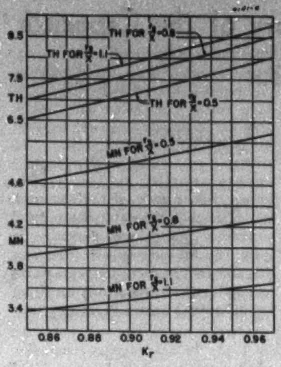

Figure 6

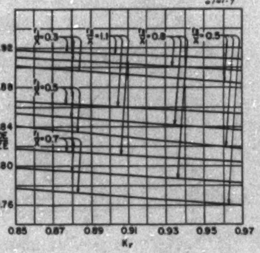

Figure 7

Figures 4–7. Curves showing data required for calculation of the maximum torque which may be expected of a single-phase induction motor

r_1=stator resistance, ohms
r_2=rotor resistance, ohms, referred to the stator

Both r_1 and r_2 represent the resistances when the motor is at its normal operating temperature. For a motor designed for a 40-degree centigrade rise, the hot resistance is 1.15 (cold resistance).

X=total leakage reactance, ohms
X_0=no load reactance, ohms

$$K_p = \frac{\text{permeance of mutual path}}{\text{permeance of mutual and primary leakage paths in parallel}}$$

$$K_s = \frac{\text{permeance of mutual path}}{\text{permeance of mutual and secondary leakage paths in parallel}}$$

$K_r = K_pK_s = (X_0 - X)/X_0$
E=impressed electromotive force, volts

To construct the circle diagram proceed in the following manner. Lay off the horizontal line $O'H$=10 inches. (Any length may be used but 10 inches is probably the most convenient. The line OE which is passed perpendicularly through $O'H$ at O' is also made equal to 10 inches for convenience.)

Calculate the voltage and current scales.

S_e=voltage scale, volts per inch, $(=E/10)$
S_1=stator current scale, amperes per inch, $(=E/10X)$
S_2=rotor current scale, amperes per inch, $(=S_1/K_p)$

Lay off

$$\left.\begin{matrix} i_m = E/X_0 \\ O'M = E/S_1X_0 \end{matrix}\right\} = 10(1-K_r)$$

Using MH as a diameter, construct the semicircle $MNLH$.

$$i_{ms} = \frac{i_mK_r}{2-K_r} \times \frac{\text{saturation factor (cross field)}}{\text{saturation factor (main field)}}$$

$$\text{Calculate } MV = \frac{E}{S_1X_0} \times \frac{K_r}{2-K_r} \times \frac{\text{saturation factor (cross field)}}{\text{saturation factor (main field)}}$$

where the saturation factor is defined as

$$\frac{\text{total ampere turns required}}{\text{ampere turns required for air gap alone}}$$

(The saturation factors for the data shown in the curves have, for convenience, been assumed equal. This is practically true for most motors.)

Locate the locked point L. The distance $LH = MH \sin^{-1} (\tan r_2/X)$

Construct a circle passing through V, L, and H

Construct OO'=0.10 inch (OO' is the main field iron loss current and is equal to main field power loss/ES_1. Its value in most normal motors lies very close to 0.10 inch)

From O lay off OE=10 inches

Choose various points T, draw lines NTH and OT, extending the lines OT to the left of OE a distance $OZ = \{(S_1r_1)/S_e\} \times OT$

Draw lines ZE.

Appendix II

Calculation of Performance Data

For each point T the following procedure is used.

Secure curves (figures 2 and 3) for desired value at $K\gamma$. Select values of MN; read values of TH, OT, and TR for proper r_2/X from figure 2; read values of MT and NT for proper value of r_2/X and OE/ZE for the proper value of r_1/X from figure 3.

1. OT—from figure 2 for proper value of K_r
2. MT—from figure 3 for proper value of K_r
3. MN—selected value, figures 2 and 3
4. NT—from figure 3 for proper value of K_r
5. TH—from figure 2 for proper value of K_r
6. TR—from figure 2 for proper value of K_r

The Cross-Field Theory of the Capacitor Motor

A. F. PUCHSTEIN
MEMBER AIEE

T. C. LLOYD
ASSOCIATE AIEE

ANALYSES of the capacitor motor operation date back to the 1920's, a pioneer effort being that of Brüderlin[1] in Europe. Work by Bloch,[2] Biermanns,[3] and others antedates that of Morrill[4] in this country whose analysis has been widely used. All of these have been based on the double revolving field theory, being extensions of that theory to the usual single-phase induction motor.

The cross-field theory has been successfully applied to plain single-phase induction motor analyses by Sumec,[5] Arnold and LaCour,[6] Steinmetz,[7] West,[8] and others, but heretofore no application of this theory has been made to the capacitor motor. The present paper is an exposition of such an analysis.

For the present purpose only two fundamental variations appear in the treatments of the cross-field theory. These concern the speed electromotive forces, built up by rotation of the rotor conductors through the rotor leakage fluxes. To elaborate on this idea, one may take the view that for the same saturation when locked and running, the machine leakage reactance is independent of rotation and that no revolving harmonic fields are present. Of the usual components of leakage flux, namely, slot, zigzag, end, and differential, the stator slot and end connection leakage are stationary in space. By the same reasoning the rotor slot and end connection leakage fluxes rotate with the rotor in space; the zigzag and differential leakage fluxes vary their distribution more or less with different rotor positions, although tacitly an average is assumed. Arnold and West imply that more accurate results are obtained if the assumption is made that the rotor leakage fluxes stand still in space, as opposed to the Steinmetz view that they move with rotation. As a working basis for the former viewpoint which will be used here, the slot, zigzag and end connection components of rotor leakage flux will all be considered as stationary, making up X_2. The differential leakage component should be charged to the stator.

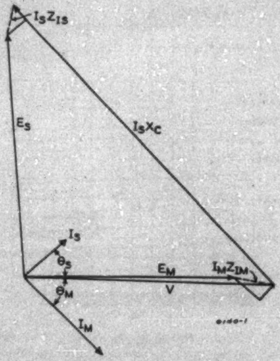

Figure 1. Vector diagram showing stator currents and voltage components

Considerable difference of opinion exists regarding the relative merits of the two classical theories for explaining single-phase induction-motor phenomena. It is not the intention of the present writers to advance the cross-field theory as being wholly superior. Each method has certain advantages and defects. For instance the cross-field theory is blind to the existence of two separate skin effects in rotor conductors and to a pulsating torque superposed on a steady torque. (This latter difficulty could be avoided by the use of instantaneous instead of vector quantities.) But differences in saturation and core losses in the two axes are much easier to visualize with the cross-field theory. And as for its application to the capacitor motor, certain other advantages will be developed and contrasted later.

Fundamental Relationships

The relationship on which the equations are based can be stated briefly as follows (assuming that the stator windings are in space quadrature):

1. The voltage applied to the main winding overcomes a local stator impedance drop and the counter electromotive force built up by the mutual flux of the main axis.

2. The stator current is the resultant of a load component reflected by transformer action from the rotor and a main-axis magnetizing current which may or may not contain an iron loss component.

3. The voltage applied to the quadrature winding (called here the start winding) overcomes the local stator impedance drop of that winding, the reactance or impedance

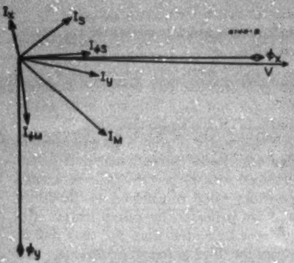

Figure 2. The stator current components and the flux vectors

drop of the capacitor in series with the winding, and the counter electromotive force built up by the mutual flux of the cross axis.

4. The stator current of the cross axis is the resultant of a load component reflected by transformer action from the rotor, and a start or cross axis magnetizing current similar to that of the main winding, but usually differing in magnitude.

5. In the rotor, the main or y-axis current results from two electromotive forces:

(*a*). The transformer voltage, opposite in phase to the stator counter electromotive force but of the same magnitude if the rotor constants are all considered in main winding terms.

(*b*). A speed voltage, resulting from the rotor conductors cutting the cross-axis mutual flux, and (as suggested by West and Arnold) the leakage flux of the rotor as well. By Kirchoff's law the vector sum of these voltages and the rotor impedance drop caused by the main axis current, equals zero.

6. In the start or x-axis of the rotor, two electromotive forces, similar to those listed above, are present:

(*a*). A transformer voltage opposite in phase to the cross-axis counter electromotive force but different in magnitude by the ratio of transformation between start winding and rotor, or start and main windings.

(*b*). A speed voltage resulting from cutting the main winding mutual and rotor leakage fluxes.

The vector sum of these voltages and the rotor impedance drop of the cross-axis rotor current equals zero.

The four fundamental equations are then (see list of symbols):

Main axis: Stator:

$$Z_M(I_M-I_y)+I_MZ_{1M}=V \tag{1}$$

Start axis: Stator:

$$Z_S(I_S-I_X)+I_S(Z_{1S}+Z_C)=V \tag{2}$$

X-axis: Rotor:

$$\frac{Z_S}{a}(I_S-I_X)+jS[-Z_M(I_M-I_y)+jI_yX_2]=aZ_2I_x \tag{3}$$

Y-axis: Rotor:

$$-Z_M(I_M-I_y)+jS\left[-\frac{Z_S}{a}(I_S-I_X)+jaI_xX_2\right]=-I_yZ_2 \tag{4}$$

These equations are extensions of West's[8] equations for the cross-field theory applied to the plain single-phase induction motor. The terms I_yX_2 and aI_xX_2 in equations 3 and 4, respectively, represent the added effect on the speed electromotive forces of cutting the rotor leakage fluxes. If these are dropped, the fundamental equations reduce to a form which Steinmetz's single-phase motor equations would yield.

By substitution, the stator components of the rotor currents, I_y and I_x, can be eliminated in these four equations, leaving two in terms of the two components of stator current. For further convenience in obtaining a final solution by determinants, the coefficients of these currents can be represented by the A, B, and C constants as shown below. Then:

$$A_1I_M+B_1I_S=C_1 \tag{5}$$

$$A_2I_M+B_2I_S=C_2 \tag{6}$$

where:

$$A_1=S\left[jZ_{1M}-X_2\left(1+\frac{Z_{1M}}{Z_M}\right)\right] \tag{7}$$

$$B_1=-\left[aZ_2+(Z_{1S}+Z_C)\left(\frac{1}{a}+a\frac{Z_2}{Z_S}\right)\right] \tag{8}$$

$$C_1=V\left[S\left(j-\frac{X_2}{Z_M}\right)-\left(\frac{1}{a}+a\frac{Z_2}{Z_S}\right)\right] \tag{9}$$

$$A_2=\left[Z_{1M}\left(1+\frac{Z_2}{Z_M}\right)+Z_2\right] \tag{10}$$

$$B_2=S\left[-aX_2+(Z_{1S}+Z_C)\left(j/a-a\frac{X_2}{Z_S}\right)\right] \tag{11}$$

$$C_2=V\left[\left(1+\frac{Z_2}{Z_M}\right)+S\left(j/a-a\frac{X^2}{Z_S}\right)\right] \tag{12}$$

Then by determinants:

$$I_M=\frac{C_1B_2-C_2B_1}{A_1B_2-A_2B_1} \tag{13}$$

$$I_S=\frac{A_1C_2-A_2C_1}{A_1B_2-A_2B_1} \tag{14}$$

From (1) and (2),

$$I_y=I_M\left(1+\frac{Z_{1M}}{Z_M}\right)-\frac{V}{Z_M} \tag{15}$$

$$I_x=I_S\left(\frac{Z_S+Z_{1S}+Z_C}{Z_S}\right)-\frac{V}{Z_S} \tag{16}$$

For rotor-locked conditions, (13) and (14), reduce to

$$I_M=\frac{V}{Z_{1M}+\left(\dfrac{Z_2}{1+\dfrac{Z_2}{Z_M}}\right)} \tag{17}$$

$$I_S=\frac{V}{(Z_{1S}+Z_C)+\dfrac{aZ_2}{\dfrac{1}{a}+a\dfrac{Z_2}{Z_S}}} \tag{18}$$

The counter electromotive forces in the separate windings are:

$$E_M=V-I_MZ_{1M} \tag{19}$$

$$E_S=V-I_S(Z_{1S}+Z_C) \tag{20}$$

The rotor input, or the power transferred across the gap, is the sum:

$$E_MI_y\cos(E_M, I_y)+E_SI_x\cos(E_S, I_x) \tag{21}$$

The power converted to mechanical form:

$$\text{Power across gap by (21)}-(I_y^2+a^2I_x^2)r_2=ST \tag{22}$$

$$\text{Net output}=\text{power converted to mechanical form}-(F\,\&\,W) \tag{23}$$

The torque in synchronous watts, (T) is the sum:

$$aE_MI_x\sin(E_M, I_x)+\frac{E_S}{a}I_y\sin(E_S, I_y) \tag{24}$$

The stator input is the sum:

$$VI_M\cos\theta_M+VI_S\cos\theta_S \tag{25}$$

The stator losses:

$$I_M^2r_{1M}=\text{copper loss in the main winding} \tag{26}$$

$$I_S^2(r_{1S}+r_C)=\text{copper loss in start winding circuit} \tag{27}$$

$$\frac{E^2M}{r_e}+\frac{E_S^2}{r_{eS}}=\text{iron losses} \tag{28}$$

The rotor losses:

$$I_y^2r_2=\text{copper loss in the }y\text{-axis} \tag{29}$$

$$a^2I_x^2r_2=\text{copper loss in the }x\text{-axis} \tag{30}$$

Some attention should be given to the matter of iron losses. In the double-field theory of Morrill, the iron losses are neg-

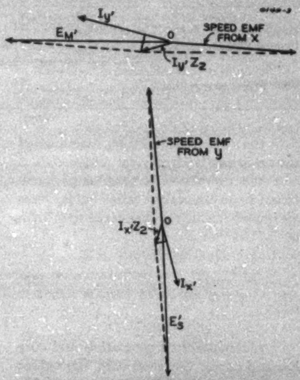

Figure 3. The rotor current and voltage vectors

lected in the equations, but good results are claimed for a correction based on consideration of these losses as external to the motor. In the use of the revolving-field analyses it has been the experience of the present writers that a lack of agreement may result between calculated and test values, particularly in the start winding under running conditions. This may be due to saturation, harmonics, or both, corrections for which are not readily introduced in the equations.

If desired, the iron losses can be considered in the symmetrical-component method of Lyon and Kingsley,[9] or in the method of Punga[10] which rests on the polyphase motor. The work of Y. Hasumi[11] on the symmetrical-component basis indicates a very simple method of introducing the iron losses in Morrill's equations by using for forward and backward impedance, respectively, the terms:

$$Z_f=\frac{1}{\frac{1}{r_0}+\frac{1}{jX_m}+\frac{1}{r_{2/s}+jX_2}}=R_f+jX_f \qquad (31)$$

$$Z_b=\frac{1}{\frac{1}{r_0}+\frac{1}{jX_m}+\frac{1}{r_{2/2-s}+jX_2}}=R_b+jX_b \qquad (32)$$

In any case the labor involved is considerable, the efforts to reduce it, such as by the method of Krondl,[12] or by tabulated form sheets and curves, have met with partial success.

In the method used here with the cross-field theory the magnetizing reactance of the main axis is jX_M. The addition of a core-loss resistance in that axis, transferred to an equivalent series value, gives an impedance of the magnetizing branch as

$$Z_M=\frac{1}{\frac{1}{r_0}+\frac{1}{jX_M}} \qquad (33)$$

Table I. Motor Running With a Slip of Four Per Cent

Method	I_M	I_S	Input and Iron	$I_M^2r_{1M}$	$I_S^2\cdot(r_C+r_{1S})$	Rotor Copper	Friction and Windage	Net Output
Morrill	$2.47\overline{\backslash 59°3'}$	$0.948\underline{/38°46'}$	221+24	12.3	14.5	11.4	13	177
Lyon & Kingsley	$2.57\overline{\backslash 55°48'}$	$0.935\underline{/38°40'}$	239	13.3	14.1	11.8	13	165
Punga	$2.57\overline{\backslash 56°30'}$	$0.948\underline{/40°50'}$	234	13.3	14.5	10.9	13	162
Cross-field	$2.64\overline{\backslash 58°36'}$	$0.954\underline{/39°0'}$	233+24	14.1	14.7	13.2	13	177 to 179.8

If widely different saturation and core losses occur in the cross-axis, the values should be modified but the magnetizing impedances in the two axes take the same form; thus:

$$Z_S=\frac{1}{\frac{1}{r_{0s}}+\frac{1}{jX_s}} \qquad (34)$$

Neglecting the iron losses, with the idea of considering them later as external to the motor, results in the reduction of Z_M and Z_S to jX_M and jX_S, respectively.

Symbols

V = applied volts. Used as reference vector
E_M = the counter electromotive force in the main axis
$Z_{1M}=r_{1M}+jX_{1M}$ = the impedance (local) of the main stator winding
Z_2 = the rotor impedance in main winding terms (local) $=r_2+jX_2$
E_S = the counter electromotive force of the start or capacitor winding
$Z_{1S}=r_{1S}+jX_{1S}$ = the local impedance of the stator start winding
$Z_C=r_C-jX_C$ = capacitor impedance
I_M = the stator current, main axis
I_S = the stator current, start axis
$I_{\phi M}$ = the magnetizing current, main axis
$I_{\phi S}$ = the magnetizing current, start axis
I_y = the stator component of the rotor current, main axis
I_x = the stator component of the rotor current, start axis
Z_S = the magnetizing impedance in the S-axis
Z_M = the magnetizing impedance in the M-axis

$$Z_S=\frac{1}{\frac{1}{r_{0S}}+\frac{1}{jX_S}}$$

$$Z_M=\frac{1}{\frac{1}{r_0}+\frac{1}{jX_M}}$$

$a=\dfrac{\text{Effective start winding turns}}{\text{Effective main winding turns}}$

$S=\dfrac{\text{Actual rpm}}{\text{Synchronous rpm}}$

s = slip

Vector Diagrams

One advantage of this analysis rests in the graphical picture which can readily be obtained for the physical relationships by vector diagrams. Figure 1 indicates the stator voltage components, as well as the usual positions of the stator currents.

In figure 2 are shown the current components and the flux vectors. The vectors $I_{\phi S}$ and $I_{\phi M}$ indicate magnetizing currents for the respective axis.

Rotor vector relationships are shown in figure 3. Rotor currents and voltages are reversed with respect to their respective positions when transferred to the stator and are indicated by prime terms. Experience indicates that I_X' may fall in either the third or fourth quadrants. The vectors shown here represent the solution of equations 3 and 4.

Summary and Comparative Results

A number of examples have been calculated by this cross-field analysis, one of which is shown in the appendix. The final data are tabulated in tables I and II along with results on the same motor as obtained through other analyses. The method throws light on the phenomena from another point of view and a favorable degree of accuracy is indicated with a competitive ease (or difficulty) of application.

To the engineer who has become thoroughly familiar with the calculation of capacitor-motor performance by the double-field theory, using convenient tabulations of equations, the use of this cross-field analysis will probably appear long and complex. However, considerable experience in handling these equations has led the writers to the belief that for time involved and complexity of calculation there is little to choose between the double-revolving and the cross-field theories. Advantages, then, for this analysis can be found chiefly in the fact that different saturation effects in the two axes can be considered more easily and that the equations result in vector diagrams which are significant in showing the effect of various design changes. This is particularly true in dealing with the conditions necessary for balanced "two-phase" operation, although detailed derivations for this application will not be carried out here. With this analysis a revolving field will exist when:

$$jI_y'=I_X' \qquad (35)$$

$$jE_M'=\frac{E_S'}{a} \qquad (36)$$

Either of these relations is sufficient as indicating that the fluxes are equal and in quadrature. With the rotor currents in terms of the main winding (35) becomes:

Table II. Starting Conditions

Method	I_M	I_S	Input and Iron	$I_M^2 r_{1M}$	$I_S^2\cdot(r_C+r_{1S})$	Starting Torque (Synchronous Watts)
Morrill	$14.2\overline{\diagdown 40^\circ 50'}$	$6.30\underline{/27^\circ 55'}$	1,796+24	406	401	755
Lyon & Kingsley	$14.0\overline{\diagdown 40^\circ 50'}$	$6.20\underline{/27^\circ 50'}$	1,750	398	390	728
Punga	$14.2\overline{\diagdown 40^\circ 45'}$	$6.28\underline{/27^\circ 40'}$	1,790	406	400	708
Cross-field	$14.2\overline{\diagdown 40^\circ 0'}$	$6.25\underline{/27^\circ 50'}$	1,800+24	408	396	759

$$jI_y = aI_X \qquad (37)$$

Also, in main winding terms:

$$jI_M = aI_S \qquad (38)$$

When this is used the total revolving magnetomotive forces are indicated as being equal and in quadrature

The problem of obtaining a true revolving field has also been discussed by Specht[12] and Trickey[14] in this country. Some interesting relationships developed by Punga,[10] Krondl,[11] and Wolf[13] do not seem to be generally known. For example when stator main and start windings have equal copper and result in equal saturation, a true revolving field is obtained at some prescribed slip s when

$a = \tan\phi$ (Punga and Krondl)

and

$X_C = (a^2+ja)Z$ (Punga)

wherein:

ϕ = the power factor angle of a two-phase motor with both phases like the main and operating at a slip s

Z = the machine impedance of phase M at a prescribed slip s, for a two-phase motor

Z_0 = the machine impedance similar to Z above, but at a slip of 2-s

All of these quantities can be obtained from the equivalent network, other equations, or the circle diagram of a two-phase motor.

Trickey's formulas for balanced condition are somewhat longer than those pertaining to the analyses quoted above although they have greater generality. Punga indicates an interesting relationship, in that under the assumptions of equal copper and saturation, I_M becomes zero when for some given value of slip, the capacitor impedance is fixed thus:

$$Z_C = -\frac{Z_0(a^2-ja)+Z(a^2+ja)}{2}$$

No one familiar with the process of designing capacitor motors can be thoroughly satisfied with the present analytical or design tools available to the designer. No convenient expression has been derived for the speed-torque curve nor for the maximum torque that can be developed. The lack of such equations as well as simplified forms of many other relationships, has proved a serious handicap. In the long run such developments result only from the examination of all available theories and viewpoints. It is the hope of the present writers that the cross-field analysis may be a step forward in aiding more useful analyses to be developed.

Appendix I

To illustrate the application of the cross-field theory an example will be worked out using the same motor for which constants are given in Morrill's[4] paper. The values for this four-pole one-fourth horsepower 110-volt motor are:

$r_{1M} = 2.02$
$r_{1S} = 5.12\times 1.18^2 = 7.13$
$r_2 = 4.12$
$r_C = 9.00$
$X_{1M} = 2.79$
$X_{1S} = 2.31\times 1.18^2 = 3.22$
$X_2 = 2.12$
$X_C(\text{running}) = -172.0$
$a = 1.18$
$X_M = 66.8$
$X_S = 92.9$

Friction and windage = 13 watts
Iron losses = 24 watts

On any given motor these constants can be obtained by the usual test methods applicable to the ordinary single-phase motor, using each winding independently. Their calculation from a design sheet involves the usual processes pertaining to the single-phase motor found in standard works on design. It is necessary to recall that the machine acts as a transformer in each of its two axes and that consideration must be given (in calculations of rotor constants) to the winding to which these constants are referred. Furthermore, as noted in this example, magnetizing reactance, and rotor resistance and leakage reactance have twice the values by the cross-field theory that they would display for the double revolving field method.

In this example, the use of an equivalent iron loss resistance will be neglected and hence Z_M and Z_S reduce to the respective values of jX_M and jX_S.

Performance will be calculated at a slip of 0.04.

From:
(7) $A_1 = -4.80+j2.00$
(8) $-B_1 = 10.14-j145.9$
(10) $A_2 = 6.367+j4.876$
(11) $B_2 = 139.1+j13.55$
(9) $C_1 = -96.2+j114.7$
(12) $C_2 = 113.5+j85.6$
(13) $I_M = 2.64\overline{\diagdown 58^\circ 36'}$
(14) $I_S = 0.954\underline{/39^\circ 0'}$
(15) $I_y = 1.55\overline{\diagdown 28^\circ 30'}$
(16) $I_x = 0.757\underline{/131^\circ 25'}$

The magnetizing current ($I\phi_M$) in the main axis $= I_M - I_y$
$= 0.015 - j1.51$

In the cross-axis ($I\phi_S$): $I_S - I_x = 1.241 + j0.034$

(19) $E_M = 102.67\underline{/0^\circ 19'}$
(20) $E_S = 113.5\underline{/91^\circ 16'}$

The rotor input:
$E_M I_y \cos(E_M, I_y) = 102.67\times 1.55\times \cos(28^\circ 30' + 0^\circ 19')$
= 140 watts from the main axis
$E_S I_X \cos(E_S, I_x) = 113.5\times 0.757\times \cos(131^\circ\ 25' - 91^\circ 16')$
= 66 watts from the cross axis

Total input to rotor = 206 watts
The rotor losses:

$I_y^2 r_2 = 1.55^2\times 4.12$ or 9.9 watts
$a^2 I_x^2 r_2 = 1.18^2\times 0.757^2\times 4.12$ or 3.3 watts
Friction and windage = 13.0 watts
Total rotor losses......26.2
Net output = 206 − 26.2 or 179.8 watts

The stator input:

$VI_M \cos\theta_M = 110\times 2.64\times \cos 58^\circ 36'$
= 151 watts
$VI_S \cos\theta_S = 110\times 0.954\times \cos 39^\circ$
= 82 watts
Total input = 233 watts

The stator losses:

$I_M^2 r_{1M} = 2.64^2\times 2.02$ or 14.1 watts
$I_S^2(r_{1S}+r_C) = 0.954^2(7.13+9)$ or 14.7 watts
Total stator losses = 28.8

Note that iron losses have been neglected throughout rather than calculated as in equation 28 and considered with the stator losses.

Output from input − losses = 233 − 28.8 − 26.2 or 178 watts.

This checks fairly well with rotor output of 179.8 watts, as calculated.

The torque from (24),

$1.18\times 102.67\times 0.757\times \sin 131^\circ 6' = 69.0$ synchronous watts

$\frac{113.5}{1.18}\times 1.55\times \sin 119^\circ 46' = 129.0$ synchronous watts

Total torque, in synchronous watts = 198.0

$$\text{Ounce feet} = \frac{112.7 \text{ synchronous watts}}{\text{synchronous rpm}}$$

The power converted to mechanical form $= ST$
$= 0.96\times 198$ or 190 watts
The output = 190 − 13 (friction and windage) = 177 watts

Some Insulator Designs Require Special Features to Insure Radio Quietness

CHARLES J. MILLER, JR.
ASSOCIATE AIEE

Synopsis: The suggested requirements for radio-free pin-type, switch and bus, and suspension insulators, if acceptable, indicate and justify from a factory testing and production viewpoint, the following conclusions as regards existing standard designs:

1. For distribution voltages up to 4,400 or even 5,500 volts, the small one-piece pin-type insulators used require no "radio-proofing", even on solidly grounded pins.

2. If there is 6 to 12 inches of crossarm in series with small one-piece pin-type insulators on low-voltage distribution lines up to 13 kv, no "radio-proofing" is needed on the insulators.

3. Standard untreated pin-type insulators used on 17 to 69-kv distribution and transmission lines have radio noise-influence voltages in the order of several thousand microvolts at a test potential about ten per cent above the usual line-to-ground voltages. "Radio-proofed" pin-type insulators, readily meeting reasonable requirements for freedom from radio interference, are available for use on lines in this voltage range.

4. Standard cemented pin-and-cap switch and bus insulators up to the 69-kv rating, with the exception of the 66-*S*-class, readily meet the suggested requirements for freedom from radio interference without any special "radio-proofing" treatment; they are inherently quiet.

5. Standard switch and bus insulators for the 66-*S*-class and the 115-kv and higher-voltage classes may require "radio-proofing" or other precautions to meet the suggested abnormally low requirements. These insulators with slight changes can be made to meet these requirements readily.

6. Regular cemented pin-and-cap suspension insulators of modern manufacture readily meet the suggested requirements for freedom from radio interference without any form of "radio-proofing"; they are inherently quiet.

RADIO interference originating on electrical power lines and substations has been studied extensively during the past 10 or 15 years by both the utility engineers and the manufacturers of equipment and materials used in construction. While it is the responsibility of the former to utilize properly the materials available for building their lines, they cannot construct a line or substation which is better than any of its component parts. Therefore, at least part of the responsibility for radio-free power lines and substations is passed on to the manufacturers of materials used in their construction.

Primarily, a power line or substation consists of several conductors which are mechanically held in place and electrically isolated from ground and from each other by means of insulators. The several conductors have a potential with respect to each other and also with respect to ground. One end of an insulator is at the potential of the attached conductor while the other end of the insulator may be at ground potential, or it may have supplementary insulation to ground such as a wood crossarm or a section of a wood pole.

In a three-phase system with a grounded neutral the maximum voltage which can appear across an insulator is the line-to-line voltage divided by 1.732. With wood in series with an insulator to ground, the voltage across the insulator itself may be somewhat less than indicated above. In a three-phase system with an ungrounded neutral an accidental grounding of one of the conductors may place the full line-to-line voltage across the insulators of the other two phases. But this is an abnormal condition which would occur only rarely and then would undoubtedly be corrected as soon as possible. Therefore, the greatest voltage which would normally appear across an insulator in a three-phase system is 0.577 of the line-to-line voltage. For convenience, this voltage is often called the "operating voltage" of the insulator.

Insulators as a Source of Radio Interference

If a power line or substation is to be free from radio interference, it is essential

---

Paper **40-144**, recommended by the AIEE committee on power transmission and distribution, and presented at the AIEE Middle Eastern District meeting, Cincinnati, Ohio, October 9–11, 1940. Manuscript submitted August 9, 1940; made available for preprinting September 18, 1940.

CHARLES J. MILLER, JR., is electrical engineer, Ohio Brass Company, Mansfield, Ohio.

Thus by three different approaches outputs of 179.8, 178.9, and 177 watts are obtained. The discrepancies are largely due to slide rule error as a ten-inch slide rule was used throughout.

With a starting capacitor of 3 ohms resistance and 14.5 ohms reactance, the starting conditions can be calculated as shown below:

$$\text{From (17)}\quad I_M = 14.2\diagdown\!\overline{40^\circ 0'}$$

$$\text{(18)}\quad I_S = 6.25\underline{/27^\circ 50'}$$

A convenient method of determining I_y and I_z is to substitute the numerical values of I_M and I_S in equations 1 and 2 respectively.

Then,

$$I_z = \frac{j78.6\, I_S}{4.86 + j81.1} \text{ or } 6.06\underline{/31^\circ 20'}$$

This is in terms of S winding; in terms of M:

$$I_z = 1.18 \times 6.06 \text{ or } 7.15 \text{ amperes}$$

Similarly:

$$I_y = \frac{j66.8 I_M}{4.12 + j68.92} \text{ or } 13.8\diagdown\!\overline{36^\circ 34'} \text{ amperes}$$

The counter electromotive force

$$E_M = jX_M(I_M - I_y)$$
$$= 63.6\diagdown\!\overline{10^\circ 47'}$$
$$E_S = jX_S(I_S - I_z)$$
$$= 38.8\overline{/57^\circ 0'}$$

The starting torque:

$$aE_M I_z \sin\,(E_M,\ I_z) = 1.18 \times 63.6 \times 6.06 \sin 42^\circ 7' \text{ or } 306$$

$$\frac{E_S}{a} I_y \sin\,(E_S,\ I_y) = \frac{38.8}{1.18}\, 13.8 \sin 93^\circ 34' \text{ or } 453$$

In synchronous watts: 306 + 453 or 759

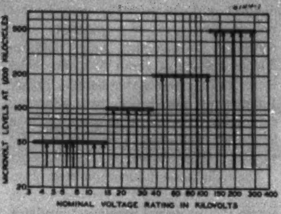

Figure 1. Proposed maximum radio noise-influence voltage levels for "radio-free" insulators

that the insulators used in its construction will not cause disturbance under normal operating conditions. On the other hand, it must not be assumed that the use of "radio-free" insulators will prevent radio disturbance from being generated by the other components used in construction.

The realization that certain types of insulators have been responsible for part of the radio noise emanating from power lines and substations has been the incentive for progressive insulator manufacturers to develop insulators which cannot cause radio disturbances when properly placed in service. Since the high-voltage pin-type insulator was the principal offender, the pioneer investigations were made on this type. (See "Behavior of High-Voltage Insulators on Radio Test," by Charles J. Miller, Jr., in *Electrical World*, March 25, 1939, pages 45–8.)

Fundamentally, the radio interference originating from insulators is caused by an electrically overstressed condition of the air adjacent to certain regions of the insulator. Fortunately, overstressed air, besides giving rise to radio interference, makes its presence known by a visual phenomenon commonly called corona, or corona discharge. This visual corona enabled the pioneer radio-interference investigators to locate the regions of electrical overstress on the pin-type insulator. It was found that these principal regions were at the conductor and tie wire and in the pin hole where thin layers of air were being subjected to intense electric fields. The obvious solution to this problem was to eliminate the air from these critical regions or to alter the design of the insulator in such a way that the intense dielectric field of the insulator between the pin and the conductor and tie wire existed wholly within the dielectric medium of the insulator and not across these layers of air.

Methods of Radio-Proofing Insulators

A conduction paint was developed which could be brushed around the head of the pin-type insulator and in the pin hole. This conduction paint altered the electric field in the critical regions and reduced the noise level of the insulator by many times. However, this paint was too temporary a remedy to be a final solution of the problem. Progressive manufacturers were not satisfied with a temporary remedy and continued the search for a permanent treatment which would last the life of the insulator.

The pin-hole problem was readily solved by cementing a zinc thimble or metal insert into the pin hole. The cement, being a semiconducting medium readily transfers the flux lines from the inner surface of the porcelain to the metal thimble.

The top of the insulator presented a bigger problem and numerous devices were used to attain the desired end. Certain designs were brought out with cemented metal hardware on top of the insulator. Some of these designs have excellent radio properties. Other designs have metallized coatings bonded to the critical area of the insulator by various means. The most recent designs utilize conducting glazes in the critical regions. This type of treatment is being very widely adopted on pin-type insulators because of its satisfactory characteristics and ease of application.

The EEI-NEMA-RMA Measuring Circuit

Along with the advancement of the art of "radio-proofing" insulators came the development of a factory means of measuring the radio-interference properties of equipment and insulators. In the early days of the art, each manufacturer devised his own method of testing and, consequently, when the time came to compare results, it was found that there was no common yardstick for measuring radio interference.

In the meantime the Edison Electric Institute, National Electric Manufacturers Association, and Radio Manufacturers Association were faced with the problem of measuring all sorts of radio interference from all types of equipment. To study the problem in general, the three organizations appointed a committee which came to be known as the "Joint Co-ordination Committee on Radio Reception of EEI, NEMA, and RMA." This committee devised a method of measuring radio noise and established various standards for these measurements. A pamphlet entitled "Methods of Measuring Radio Noise" was published in December 1935 by the joint committee. The latest publication by this committee (EEI Publication No. *G*9—NEMA Publication No. 107—RMA Engineering Bulletin No. 32) is entitled "Methods of Measuring Radio Noise, 1940" and was published in February 1940.

The joint committee devised a circuit to be used for high-voltage devices. This circuit was adopted by leading insulator manufacturers in 1937 and has been the recognized method of test since. (See "Establishes Method of Measuring Radio Interference," by Charles J. Miller, Jr.,

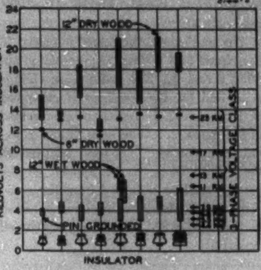

Figure 2. Kilovolts necessary to produce a radio noise-influence voltage of 50 microvolts on small one-piece pin-type insulators with the pin grounded and with wood in series with the insulator

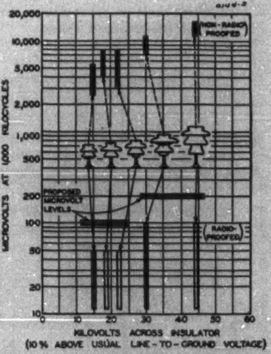

Figure 3. Radio noise-influence voltages from regular pin-type insulators at a test voltage about ten per cent above the usual line-to-ground voltage

in *Electrical World*, March 11, 1939, pages 48–50.)

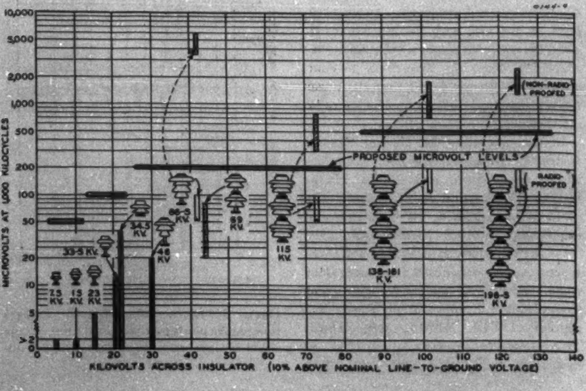
The insulator to be tested is placed in the circuit and a 60-cycle potential is applied across it. The radio noise voltage generated by the insulator is measured with the radio noise meter and is expressed in "microvolts." The term "radio noise-influence voltage" has been adopted as the official name to be applied to the voltage reading obtained from the radio noise meter when the specimen is tested in the EEI-NEMA-RMA recommended circuit.

Requirements for Radio-Free Insulators

To be free of radio interference, insulators must meet certain requirements when tested in the EEI-NEMA-RMA circuit. Based on field experience and known characteristics of available "radio-free" insulators, the majority of manufacturers of high-voltage insulators have suggested radio noise-influence voltage levels which will insure freedom from interference of various classes of insulators under service conditions.

Radio interference originating on a power line may be transferred to a nearby antenna by direct coupling between the power line and antenna, or it may be carried an appreciable distance along a low-voltage distribution line and then be transferred to a receiving antenna. (See "Sources of Radio Interference and How to Eliminate Them," by Paul M. Ross, in *Electric Light and Power*, September 1939, pages 38–9.) In the latter case, coupling must exist between the power line and the low-voltage distribution line and also between the distribution line and the antenna.

Figure 4. Radio noise-influence voltages from regular pin-and-cap switch and bus insulators at a test voltage about ten per cent above the nominal line-to-ground voltage



The farther the distribution line or the antenna from the power line, the smaller is the transfer of radio interference. In general, the higher the voltage of a power line, the greater is its distance from low-voltage distribution lines and antennas. Accordingly, it seems quite reasonable to select a maximum permissible microvolt radio noise level in keeping with the voltage of the line.

Low-voltage distribution lines up to the 13-kv class cover widespread areas and are more or less closely coupled to distribution networks supplying individual homes. It is felt that a maximum radio noise-influence voltage of about 50 microvolts for insulators used on these lines will insure freedom from radio noise provided the radio noise-influence voltages of all other components of the line are also below equally satisfactory levels. Obviously, disturbance on a power line arising from sources other than insulators cannot be blamed on the insulators, nor can "radio-free" insulators suppress radio interference arising from these other sources.

Power lines in the 17 to 34.5-kv classes are, in general, not as closely coupled to the distribution networks and, therefore, a maximum radio noise-influence voltage of about 100 microvolts seems to be a reasonable level. In the range from 46 to 115-kv classes, a level of 200 microvolts should provide adequate protection from radio interference. Transmission lines in the 138 to 287-kv classes seldom parallel lower-voltage lines for any appreciable distance and are generally more or less remote from areas of population. Accordingly, a maximum radio noise-influence voltage of about 500 microvolts seems to be a reasonable figure. Figure 1 illustrates graphically these proposed maximum radio noise-influence voltage levels for radio-free insulators for the various voltage classes.

The radio noise-influence voltage of an insulator is dependent upon the voltage across it. In actual service an insulator is subjected to the line-to-ground or operating voltage. Every transmission line has a "nominal" voltage rating which may be slightly different than the actual voltage. Furthermore, the actual voltage on a transmission line may be higher at the sending end than at the receiving end. To compensate for possible voltage variations from the nominal value, it seems quite logical to subject the insulator to a test voltage about 10 per cent higher than the nominal line-to-ground voltage when testing it in the EEI-NEMA-RMA circuit.

With a standard method for measuring the radio noise-influence voltage produced by an insulator and with a set of requirements which must be fulfilled by a "radio-free" insulator, the insulator manufacturer has at his disposal a radio-interference yardstick with which he can judge the merits of the insulators he manufactures.

Radio Noise-Influence Voltages of Various Types of Insulators

Having a definite yardstick for measuring the radio interference properties of insulators, a survey of available insulators of all types provides an interesting study. Briefly, such a study leads to the conclusion that certain types of insulators which have been manufactured for years require no special "radio-proofing" to meet the suggested requirements for freedom from radio interference; they are inherently quiet.

Conducting glazes provide effective "radio-proofing" on pin-type insulators. However, it does not necessarily follow that conducting glazes are required on all designs and classes or that they provide the only effective means of "radio-proofing" an insulator. For example, pin-type insulators which are "radio-proofed" with metallized coatings or cemented hardware are available.

SMALL ONE-PIECE PIN-TYPE INSULATORS

Small one-piece pin-type insulators are commonly used on low-voltage distribution circuits. In many cases these insulators are mounted on wood crossarms. This provides a section of wood in series with the insulator to ground or between phases. The voltage divides in proportion to the impedance of the insulator and that of the section of wood, thereby reducing the potential across the insulator from the operating voltage to a lower value. This means that the radio noise-influence voltage to ground from a given insulator will be lower with a section of wood in series with it than with the pin grounded.

A "radio-proof" power line is one which does not interfere with radio reception in nearby homes. It makes no difference how the "radio-proofing" is accomplished so long as the desired results are attained. Small "radio-proofed" pin-type insulators are available for even the lowest-voltage lines. However, before proceeding with the application of "radio-proofed" insulators to these voltage lines, it might be well to stop for a moment and consider the limitations of the old reliable "non-radio-proofed" insulators used for years on the lower-voltage lines.

Figure 2 shows the kilovolts across the insulator necessary to produce a radio noise-influence voltage of 50 microvolts on several different sizes of insulators. Since no two insulators of even the same size give exactly the same results on test, the bands in which all of the test values fall are given. With the pin grounded, the 50-microvolt level falls between 3 and 6 kv for all of the insulators.

Numerous tests were made with 12 inches of dry wood in series with the insulator and a wide range of kilovolt levels was found, ranging from about 12 to 21 kv. A single test was made on each size insulator with 6 inches of dry wood in series with the insulator and the kilovolt levels ranged from 11.5 to 13.5 kv.

Tests were made on one size insulator with 12 inches of very damp wood in series with it. Two samples of wood crossarm were used. These crossarms had been lying outside the laboratory all winter and accordingly were very wet inside, probably much more so than crossarms in service on poles. In spite of this, these crossarms added 2 or 3 kv to the 50-microvolt level voltage.

In any power line, the voltage across the insulator is determined by the operating voltage of the line. In a three-phase system, the voltage across the insulator is generally considered to be the line-to-line voltage divided by the $\sqrt{3}$. It is this voltage which may cause radio interference from the insulator. In figure 2 the line-to-neutral voltage is shown for several nominal operating voltages.

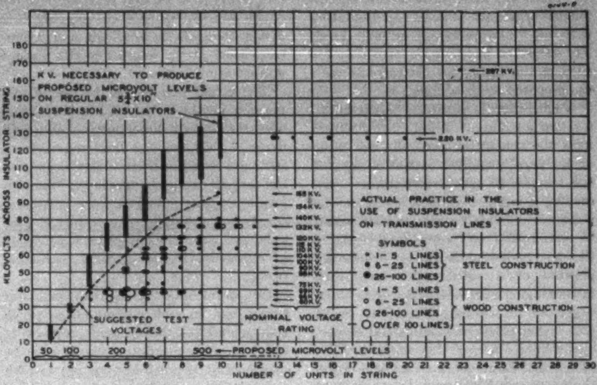


Figure 5. A comparison between the voltages applied to suspension insulator strings in actual practice and voltages necessary to produce the proposed microvolt levels

Up to and including 4,400-volt lines, not a single insulator would produce as much as 50 microvolts of radio interference even with the pins bonded. Accordingly, the ordinary plain insulator used for years is entirely adequate as regards radio interference and nothing can be gained by using "radio-proofed" insulators on 4,400-volt and lower-voltage power lines.

When there is 6 to 12 inches of dry crossarm in series with the insulator, the 50-microvolt level occurs at such a high voltage that even 13 and 17-kv lines are free from radio interference with the ordinary plain insulator. The actual improvement provided by the wood depends almost entirely upon its moisture content. Real wet wood, a condition existing for infrequent and short periods, may provide only a few kilovolts improvement. In figure 2, wet wood adds from 2 to 4 kv to the 50-microvolt level voltage, but this is enough to assure freedom from radio disturbance on 7.5-kv lines. Crossarms in service exposed to the air would probably never be as wet as the arms tested. Accordingly, it seems reasonable to expect that under average conditions 12 inches of wood in series with the insulator will assure freedom of radio interference from power lines operating at 7.5 kv to ground (13 kv, three phase) and below without the necessity of using "radio-proofed" insulators.

High-Voltage Pin-Type Insulators

The standard pin-type insulators used on 17 to 69-kv distribution lines have radio noise-influence voltages in the order of several thousand microvolts at a test voltage ten per cent above the nominal line-to-ground voltage for which the insulators are commonly used. Figure 3 shows the range of radio noise-influence voltages for five of the popular sizes of pin-type insulators. The proposed microvolt levels are also shown. Obviously, the conventional pin-type insulator cannot qualify as a radio-free pin-type insulator.

Dry wood crossarms in series with these insulators will reduce the noise level a marked degree but in general the reduction is not sufficient to approach the suggested microvolt levels. The only practical permanent solution for the radio-interference problem on the higher-voltage distribution lines is to use "radio-proofed" pin-type insulators which have been manufactured for the purpose. Several types of "radio-proofed" insulators which readily meet the suggested requirements are available. The use of conduction paint or other temporary means of suppression offer an opportunity for satisfactory treatment of existing lines where reinsulation by improved designs cannot be justified.

Switch and Bus Insulators

Generally accepted apparatus voltage ratings have been assigned to the various sizes of switch and bus insulators. The radio noise-influence voltages measured on the various switch and bus insulators at a 60-cycle test voltage about ten per cent above the voltage rating divided by the $\sqrt{3}$ are shown by the bands in figure

4. These are the results of test on the regular cemented pin-and-cap insulators with no "radio-proofing" of any kind. The suggested microvolt levels shown for each of the insulators corresponds with the proposed levels of figure 1.

A substation is generally restricted to a rather small area. Lines leading to and from the substation generally are more or less poorly coupled with it as regards the transfer of radio interference. Accordingly, higher microvolt levels may be permissible within the station than would be permissible on power lines running through residential districts. Other components of a substation which tend toward higher microvolt levels than those suggested for insulators seem to prove that higher levels can and should be permitted in substations. The ease with which switch and bus insulators can be brought to the suggested microvolt levels appears to be the only justification for these ultraconservative values being considered.

A study of figure 4 reveals the important fact that every one of the switch and bus insulators up to and including the 69-kv class, with the exception of the four-part single-unit 66-*S*-kv insulator, has a radio noise-influence voltage which is less than the suggested allowable value for "radio-free" insulators. This means that regular switch and bus insulators up to the 69-kv class, excepting the 66-*S*-class, do not need any special "radio-proofing" treatment to make them quiet; they are inherently so.

The 66-*S*-class insulator definitely requires a "radio-proofing" treatment if the suggested microvolt level is to be met. It has been successfully "radio-proofed" by slight revisions and its radio noise-influence voltage is well below the permissible 200 microvolts at a test voltage 10 per cent above the nominal line-to ground voltage. These revised designs are now the standard products of leading manufacturers.

The stacking insulators used in the 115-kv class and above give radio-influence voltages which exceed the proposed microvolt levels. To meet these suggested levels, slight revisions have been necessary to "radio-proof" these insulators in manufacture.

Suspension Insulators

No definite voltage ratings have been assigned to suspension insulators. In fact a survey of general practice over the entire country reveals an amazing lack of consistency in the application of various suspension string lengths to the various voltage classifications.

The actual practice in the use of suspension insulators on 612 transmission lines throughout the country is shown in figure 5. Of the 612 lines represented, 291 have wood in their construction and 321 are all-steel construction. This information was gathered from published charts and tabulations in technical journals, and, though incomplete, it probably is representative of existing construction.

By considering the shortest insulator string used in each voltage class, which also represents the highest voltage to which a given insulator string may be subjected, it is possible to assign to each string length a maximum microvolt level which is consistent with the proposed levels of figure 1. The proposed microvolt levels assigned to each string length are indicated at the bottom of figure 5.

The kilovolts necessary to produce the proposed microvolt levels for the different string lengths of regular cemented pin-and-cap suspension insulators of modern manufacture are shown by the bands in figure 5. These values are given only for string lengths up to ten units as this was the upper limit of testing equipment available at the time the tests were made. Higher-voltage equipment is now available.

In every case, the minimum kilovolts necessary to produce the proposed microvolt level is well above the highest voltage to which the given string would be subjected in service. In other words, at the highest operating voltage the radio noise-influence voltages from standard unaltered and untreated suspension insulators are less than the proposed microvolt levels for freedom from radio interference. Accordingly, it seems unnecessary to apply special treatment to standard cemented pin-and-cap suspension insulators; they are inherently "radio-free."

It is possible to assign to each string length a 60-cycle test voltage which represents the severest conditions to which the string may be subjected. To be consistent the test voltage assigned to each string length should bear some relation to other string lengths. One such set of assigned values is connected by a curve in figure 5. This curve is more or less the upper envelope of the points representing the suspension insulator applications. There seems to be no reason for placing this curve much higher as this would increase the severity of the radio test on suspension insulators and it would benefit no one.

In spite of the excellent radio characteristics of suspension insulators, conduction glaze has been applied both at the cap and in the pin hole. The cap treatment has increased the visual corona voltages materially. The treatment in the pin-hole area, however, has not proved as successful as at the cap, and in long strings the corona voltage at the pin of the line unit is in general lower than the corona voltage for the corresponding nontreated suspension insulators. The radio noise-influence voltages are generally about the same for the treated and nontreated insulators but there seems to be a tendency for the treated insulators to come lower. The failure of the conduction glaze treatment to provide the improvement found in its other applications is probably due to the configuration of the dielectric field in the pin hole and the inability of the conducting glaze, which must necessarily be applied only to the surface of the porcelain, to alter this field sufficiently to relieve the stress on the adjacent air.

On practically all lines, there are conductor and hardware members operating at high voltages, including clamps or other means for attaching the conductors to the insulators, reinforcing devices such as armor rods, vibration dampers, and similar special items. On a "radio-free" transmission line there must be no disturbances originating from the hardware. When such disturbances occur, they are caused by electrically over-stressed air adjacent to sharp corners or edges of the hardware. Such sources of noise generate a great amount of radio disturbances. Laboratory tests show that when such a disturbance starts, the radio noise-influence voltage jumps abruptly to several hundred microvolts and a small increase in the 60-cycle test voltage is accompanied by a big increase of the radio noise. It is essential in "radio-proofing" a transmission line to be sure that the hardware is adequately designed as well as the insulators.

Performance Calculations on Repulsion Motors

P. H. TRICKEY
MEMBER AIEE

Synopsis: A method of calculating the performance of repulsion motors is developed for the purpose of predetermining the torques and currents, especially for repulsion-start, induction-run motors during the starting period. The method is based on the cross-field theory presented by H. R. West. It is developed along similar lines to the single-phase calculation method presented by C. G. Veinott,[2] and is intended for use in connection with it. The paper presents also the results of investigation showing the effects of varying the several motor constants, and a method of determining the effect of brush resistance.

IN a paper presented a number of years ago, H. R. West developed methods of calculating the performance of single-phase induction and repulsion motors, based on the cross-field theory. In 1932, C. G. Veinott further developed the method for single-phase motors, from the point of view of routine calculation, and presented a calculation sheet for this purpose which is now in use in the engineering departments of many motor companies.

It is the purpose of this paper to develop the repulsion-motor method in the same manner, and to offer a calculation sheet of the same general form as that presented by Mr. Veinott. It has been developed particularly for use in conjunction with it in the design of repulsion-start, induction-run motors, but may, of course, be used for ordinary repulsion-run motors.

Repulsion-Motor-Performance Calculations

The circuits of the repulsion motor may be represented by figure 1. The development of the method consists in writing the equations of voltages in the three circuits of the motor in accordance with Kirchhoff's law, and solving these equations for the motor currents and torque. The problem then becomes one of algebraic transformation into a form most suitable for routine solution. This particular derivation has had several important objectives. The first, of course, is speed. Repulsion motors are usually fractional horsepower, and unless the calculation is quickly and easily made, it is more economical to rewind a sample motor once or twice. The second objective is simplicity and clarity. It often happens that repulsion-motor designs come at infrequent intervals in the course of designing many other types, usually split-phase or polyphase. It is desirable that the designer be able to proceed immediately into a calculation without any preliminary "brushing up" on the method. Another objective in this case is the possibility of calculating torques and speeds without calculating currents or inputs. This is desirable with repulsion-start, induction-run motors, in obtaining the starting and pull-up torques.

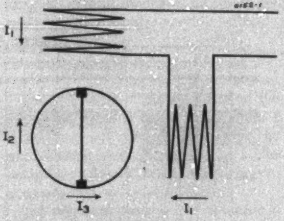

Figure 1. Schematic diagram of the repulsion motor

As will be shown later, one of the characteristics of the repulsion motor is that its starting torque is a maximum with no current in the coils short-circuited by the brushes. This would occur with infinite brush resistance. The method has been so arranged that a simple calculation with infinite brush resistance is easily made as a check on the loss of torque due to the short-circuit current.

All of the assumptions and details in the papers of Mr. West and Mr. Veinott hold for this method also. The angle of hysteretic lag between the flux and the magnetomotive force is assumed to be zero. Sinusoidal voltages and currents are assumed. The flux is assumed proportional to the current and magnetomotive force.

The method involves choosing a value of speed, and calculating the performance at that speed. The currents and torques are calculated independently of each other. Although it is possible by this method to obtain a vector solution for the primary current, and from the power component derive the watts input, it was felt as in the case of Mr. Veinott's calculation sheet that a more accurate value would be obtained by adding the losses to the output.

Due to the most frequent use of this method being at the lower speeds and greater currents, it was decided to subtract the iron loss from the output in the same manner as the friction loss.

There is one point in the calculation where it is assumed that the primary and secondary reactances are equal, that is, $x_1 = x_3$. This occurs in calculating the constant H_1,

for $x_1 \neq x_2$,

$$H_1 = \frac{r_1}{X_0}\left(1 + \frac{r_2}{r_3}\right) + \frac{r_2}{X_0}\left(\frac{X_m + x_1}{X_m + x_2}\right)$$

for $x_1 = x_2$,

$$H_1 = \frac{r_1}{X_0}\left(1 + \frac{r_2}{r_3}\right) + \frac{r_2}{X_0}$$

For all ordinary work the second formula is used, but if desired the first one may be followed. Figure 2 shows the small change in performance when the reactances are not equal.

Figure 12 shows the form of the calculation sheet and an illustrative example.

The Effect of Changing the Motor Constants

A number of calculations have been made showing the effect of changing the different constants of the motor. Figure 2 has already been mentioned showing the effect of transferring the reactance from stator to rotor or vice versa. Figure 3 shows the effect of increasing or decreasing the total leakage reactance. The improvement in a motor with increased numbers of slots is largely the result of decreased reactance.

The speed-torque curves of figure 4 show little change with variation of the open-circuit reactance, the greatest change being in the current and power factor. However, it will be noticed that as X_0 decreases, there is finally a reduc-

Paper 40-152, recommended by the AIEE committee on electrical machinery, and presented at the AIEE Middle Eastern District meeting, Cincinnati, Ohio, October 9–11, 1941. Manuscript submitted October 8, 1937; made available for preprinting September 4, 1940.

P. H. Trickey is section head, fractional-horsepower motor design, Diehl Manufacturing Company, Elizabethport, N. J.

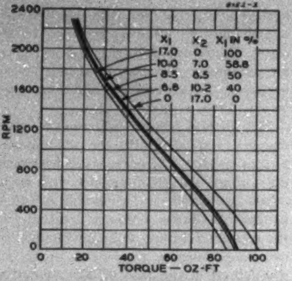

Figure 2. Effect of distribution of leakage reactance between primary and secondary

tion in torque, and it will be found that as the size of the motor decreases or the number of poles becomes greater, this effect will become quite prominent. This is the result of the increased primary impedance drop which reduces the voltage remaining to supply the air-gap flux.

No curves are given for the effect of changing the motor turns, for the result is the same as that obtained by varying the applied voltage, that is, the torques vary as the square of the voltage. Also, any change in the primary resistance has much the same effect, that is, the impedance drop varies and with it the remaining useful voltage.

Figure 5 showing the effect of secondary resistance is somewhat different than for the induction motor, for even at standstill the torque is decreased with increased rotor resistance.

Figure 6 illustrates several interesting points. As will be shown later, r_2 is the resistance of the useful part of the armature, which is made up of a number of coils in series with the brushes. r_3 is the resistance of the short circuits caused by the brushes, and is usually made up of one coil only, in series with two halves of a brush. The several short-circuited coils have the effect of operating in parallel. Figures 6 and 7 show very clearly that the higher r_3, the more desirable the speed-torque characteristics. Whereas, figure 5 shows that r_2 should be decreased for improvement. The problem then is one of increasing r_3 without at the same time increasing r_2. To do this by increasing the resistance of the brush itself is not advantageous beyond a certain point, for although r_3 may be increasing much faster than r_2, a point will be reached when any further increase in r_2 will result in too low pull-up torque. The usual method is to increase the number of coils and commutator bars, which makes the brush resistance a smaller percentage of r_2, and a greater percentage of r_3. It will be noted that r_3 has comparatively little effect on the torque at 75 per cent of synchronous speed, which is the usual operating speed of the short-circuiter, while effecting the starting torque almost directly.

A point of academic interest is obtained with r_2 very low and equal to r_3. Under these conditions, the motor has no starting torque, and operates exactly like a single-phase induction motor. This abnormal condition would be obtained with very wide low-resistance brushes, or with double the regular number of brushes, spaced 45 electrical degrees apart.

It might be noted at this point, that r_3 inherently varies with commutator position as the number of coils short-circuited by the brush changes. For instance, suppose the brush thickness equals one commutator bar. In this case, when the brush is exactly over the bar no coils are short-circuited, and r_3 is infinite. When the brush is touching two bars, there is one coil short-circuited under each brush. Thus, r_3 varies from some definite value to infinity, as the rotor passes through one commutator bar pitch. This is the usual case, but supposing the brush is a little wider and can touch three bars at some positions. In this case, r_3 will vary from the worst or lowest value of the narrow brush, to a value which is only half as much.

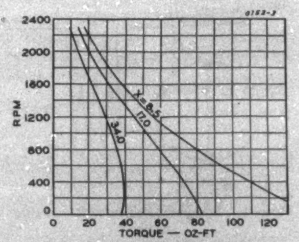

Figure 3. Effect of leakage reactance

The most outstanding variable in the repulsion motor is the brush shift. Figures 8 and 9 illustrate the effect on the starting and running torques, respectively. It would, of course, be desirable to operate at the point of maximum starting torque. However, the actual dimensions of the brush shift are not very large, particularly in four-, six-, and eight-pole motors, and to be safe under conditions of manufacturing variations, the brush shift is usually chosen on that side of the peak value corresponding to more shift. This side of the curve is less steep, and if the brush location is not exactly correct, the starting torque will not decrease as much.

Brush Resistance

There is no difficulty in calculating the primary resistance and the reactances of the repulsion motor, but it might be well to discuss the calculation of the secondary resistances r_2 and r_3. One of the difficulties in the design of repulsion motors has been the calculation of that part of r_2 and r_3 caused by the contact resistance of the brushes.

$$r_{2I}=\left[\frac{CKw_m}{2\,tpc\,Kw_{2I}}\right]^2\frac{r_c}{N_c} \tag{1}$$

$$r_2=\left[\frac{CKw_m}{2\,tpc\,Kw_{2R}N_c/a}\right]^2\frac{\dfrac{r_cN_c}{a}+\dfrac{r_b4}{A_b}}{a} \tag{2}$$

$$r_3=\left[\frac{CKw_m}{2\,tpc\,Kw_m}\right]^2\frac{r_c+\dfrac{r_b4}{A_b}}{a} \tag{3}$$

where

r_{2I} = rotor resistance referred to the primary when all commutator bars are short-circuited together, and operating as an induction motor
r_2 = rotor resistance as a repulsion motor
r_3 = rotor resistance of the short-circuited coils
r_c = resistance per coil of rotor
r_b = brush contact resistivity, see figure 10
CKw_m = total effective series conductors of primary
tpc = turns per coil in rotor
N_c = number of coils on rotor
a = number of parallel paths in rotor
Kw_{2I} = rotor winding factor (pitch times distribution factor) with commutator short-circuited

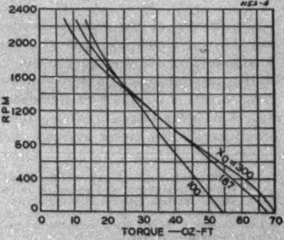

Figure 4. Effect of X_0, the "open-circuit reactance"

Kw_{2r} = rotor winding factor operating repulsion
Kw_3 = winding factor of short-circuited coils
A_b = brush area (minus mica area) in square inches

Equation 1 gives the value of rotor resistance r_{2i} to be used for calculation when the motor is operating as an induction motor with all the commutator bars short-circuited. Equation 2 should be used for the rotor resistance r_2 when operating repulsion, and equation 3 should be used for r_3. It can be shown that for uniform coil rotors, Kw_{2i} and Kw_{2r} are equal, and it may then be noted that when the brush resistance is equal to zero, r_{2i} equals r_2. It is, therefore, convenient to obtain the value r_2 from the formula given below.

$$\underset{\text{repulsion}}{r_2} = \underset{\text{induction}}{r_{2i}} \frac{R_A+R_B}{R_A} \qquad (4)$$

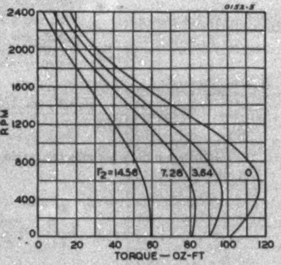

Figure 5. Effect of rotor resistance

where

$$R_A = \frac{r_c N_c}{a} \text{ and } R_B = \frac{r_b 4}{A_b}$$

The value for r_3 may be obtained in a similar manner.

$$r_3 = r_{2i}\left[\left(\frac{r_c+R_B}{r_c}\right)\frac{N_c}{a}\,\frac{DF_{2i}}{DF_3}\right] \qquad (5)$$

where

DF_{2i} = distribution factor when operating induction (approximately 0.637)
DF_3 = distribution factor for short-circuited coils (usually 1.0)

Figure 10 shows the effect of current density on the brush resistance. To be exact, it would be necessary to use a different value of r_3 corresponding to the current density, for each point of a calculated speed-torque curve. In practice, r_3 is usually high enough so that an average value may be used for the whole curve. It will be found that the brush current densities for most repulsion-start induction-run motors are very high reaching several hundred amperes per square inch during the starting period.

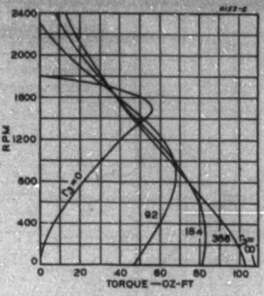

Figure 6. Effect of brush short-circuit resistance

Conclusions and Acknowledgments

The derivation of the equations of the calculation sheet is given in appendix I along with an example illustrating its use. Derivations relating to the motor constants and brush resistances are given in appendix II.

The brush resistance curve of figure 10 is from data furnished by the National Carbon Company.

Partial List of Symbols

(All secondary values are referred to the primary.)

E = applied voltage
I_1 = line or primary current
I_2 = secondary current in main field
I_3 = secondary current in cross field (brush short-circuit current)
r_1 = primary resistance
r_{2i} = rotor resistance as induction motor
r_2 = resistance of main field-rotor circuit
r_3 = resistance of cross-field rotor circuit (brush short-circuit resistance)
X_m = mutual or magnetizing reactance of stator and rotor windings
x_1 = leakage reactance of primary
x_2 = leakage reactance of each rotor circuit
f = frequency
S = speed as a fraction of synchronism
A = angle of brush shift in electrical degrees
Φ_t = flux in transformer axis (main field)
Φ_f = flux in field axis (cross field)

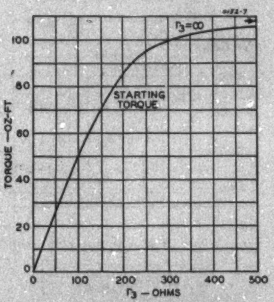

Figure 7. Effect of brush short-circuit resistance on starting torque

Appendix I

Derivation of Repulsion Motor Performance Equations

The circuits of a repulsion motor may be represented schematically by the diagram of figure 1. If A is the angle of brush shift in electrical degrees, the equations for the three circuits may be set up according to Kirchhoff's law. Mr. West[1] writes these equations as given below:

$$E = jX_m(I_1\cos^2 A - I_2\cos A) + jX_m(I_1\sin^2 A - I_3\sin A) + (r_1+jx_1)I_1$$

$$0 = -jX_m(I_1\cos A - I_2) + (r_2+jx_2)I_2 + SX_mI_1\sin A - S(X_m+x_2)I_3$$

$$0 = -jX_m(I_1\sin A - I_3) + (r_3+jx_2)I_3 - SX_m(I_1\cos A - I_2) + Sx_2I_2$$

Solving these equations for the three currents,

$$I_1 = E \times \frac{[r_2r_3 - (1-S^2)(X_m+x_2)^2 + j(r_2+r_3)(X_m+x_2)]}{U'+jW'}$$

$$I_2 = EX_m \times \frac{[-Sr_3\sin A - (1-S^2)(X_m+x_2)\cos A + jr_3\cos A]}{U'+jW'}$$

$$I_3 = EX_m \times \frac{[Sr_2\cos A - (1-S^2)(X_m+x_2)\sin A + jr_2\sin A]}{U'+jW'}$$

where

$$U' = -r_3X_m^2\cos^2 A - r_2X_m^2\sin^2 A - (r_2+r_3)(x_1+x_2)X_m - (r_2+r_3)x_1x_2 + r_1r_2r_3 - (1-S^2)r_1(X_m+x_2)^2$$

$$W' = r_1(r_2+r_3)(X_m+x_2) + r_2r_3(X_m+x_1) + S(r_3-r_2)X_m^2\sin A\cos A - (1-S^2)\times(X_m+x_2)[X_m(x_1+x_2)+x_1x_2]$$

Torque in synchronous watts =

$$\frac{E^2X_m^2}{U'^2+W'^2}\left\{(r_3^2-r_2^2)(X_m+x_2)\sin A\cos A + (r_3\sin^2 A + r_2\cos^2 A)[-Sr_2r_3 + S(1-S^2)\times(X_m+x_2)^2]\right\}$$

It is advisable, at this point, to divide the numerator and denominator of the current equations by $(X_m+x_2)^2$ and the torque equation by $(X_m+x_2)^4$.

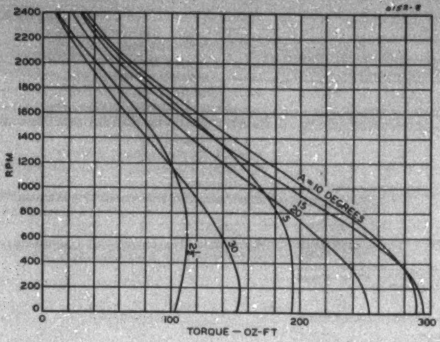

Figure 8. Effect of brush shift on speed-torque curves

A = Brush shift in electrical degrees

Then

$$I_1=E\frac{\dfrac{r_2r_3}{(X_m+x_2)^2}-\dfrac{(1-S^2)(X_m+x_2)^2}{(X_m+x_2)^2}+j\dfrac{(r_2+r_3)(X_m+x_2)}{(X_m+x_2)^2}}{U+jW}$$

$$I_2=\frac{EX_m}{(X_m+x_2)}\,\frac{\dfrac{-Sr_3\sin A}{X_m+x_2}-(1-S^2)\dfrac{X_m+x_2}{X_m+x_2}\times\cos A+j\dfrac{r_3}{X_m+x_2}\cos A}{U+jW}$$

$$I_3=\frac{EX_m}{(X_m+x_2)}\,\frac{\dfrac{Sr_3}{X_m+x_1}\cos A-(1-S^2)\times\dfrac{X_m+x_2}{X_m+x_2}\sin A+j\dfrac{r_3}{X_m+x_2}\sin A}{U+jW}$$

$$T=\frac{\dfrac{E^2X_m^2}{(X_m+x_2)^2}}{U^2+W^2}\left\{\frac{(r_2^2-r_3^2)(X_m+x_2)}{(X_m+x_2)^2}\times\sin A\cos A+[r_2\sin^2 A+r_3\cos^2 A]\times\left[-S\frac{r_2r_3}{(X_m+x_2)^2}+S(1-S^2)\frac{(X_m+x_2)^2}{(X_m+x_2)^2}\right]\right\}$$

where

$$U=-r_2\frac{X_m^2}{(X_m+x_2)^2}\cos^2 A-r_3\frac{X_m^2}{(X_m+x_2)^2}\times\sin^2 A-\frac{(r_2+r_3)(x_1+x_2)X_m}{(X_m+x_2)^2}-\frac{(r_2+r_3)x_1x_2}{(X_m+x_2)^2}+\frac{r_1r_2r_3}{(X_m+x_2)^2}-(1-S^2)r_1\frac{(X_m+x_2)^2}{(X_m+x_2)^2}$$

$$W=\frac{r_1(r_2+r_3)(X_m+x_2)}{(X_m+x_2)^2}+\frac{r_2r_3(X_m+x_1)}{(X_m+x_2)^2}+\frac{S(r_3+r_2)X_m^2\sin A\cos A}{(X_m+x_2)^2}-(1-S^2)\times\frac{(X_m+x_2)}{(X_m+x_2)^2}[X_m(x_1+x_2)+x_1x_2]$$

$$\Phi_f=\frac{\sqrt{2}I_2(X_m+x_2)}{2\pi fN10^{-8}}\left[\frac{X_m}{(X_m+x_2)}\frac{I_1}{I_2}\sin A-1\right]$$

$$\Phi_t=\frac{\sqrt{2}I_3(X_m+x_2)}{2\pi fN10^{-8}}\left[\frac{X_m}{(X_m+x_2)}\frac{I_1}{I_3}\cos A-1\right]$$

From this point on, we will depart from Mr. West's derivation, and method of attack. For simplicity of calculation, and so that the designer may know just how the motor losses are distributed, we will calculate the magnitudes alone of the currents, and obtain the input from the sum of output and losses. In order to simplify the above equations, let us arbitrarily define

$$X_0=X_m+x_2$$

$$K_p=\frac{X_m}{X_m+x_2}=\frac{X_m}{X_0}$$

$$K_r=K_p^2=\frac{X_m^2}{X_0^2}=\frac{X_m^2}{(X_m+x_2)^2}$$

$$I_1=E\frac{\dfrac{r_2}{X_0}\dfrac{r_3}{X_0}-(1-S^2)+j\dfrac{(r_2+r_3)}{X_0}}{U+jW}$$

$$I_2=EK_p\,\frac{-S\dfrac{r_3}{X_0}\sin A-(1-S^2)\cos A+j\dfrac{r_3}{X_0}\cos A}{U+jW}$$

$$I_3=EK_p\,\frac{S\dfrac{r_3}{X_0}\cos A-(1-S^2)\sin A+j\dfrac{r_3}{X_0}\sin A}{U+jW}$$

$$T=\overline{EK_p}^2\left\{\frac{\dfrac{(\sqrt{r_3^2-r_2^2})^2}{X_0}\sin A\cos A+[r_2\sin^2 A+r_3\cos^2 A]\times\left[-S\dfrac{r_2r_3}{X_0X_0}+S(1-S^2)\right]}{U^2+W^2}\right\}$$

$$U=-r_2K_r\cos^2 A-r_3K_r\sin^2 A-\frac{(r_2+r_3}{X_0}\left[\frac{x_1X_m+x_2X_m+x_1x_2}{(X_m+x_2)}\right]+\frac{r_1r_2r_3}{X_0X_0}-(1-S^2)r_1$$

$$W=\frac{r_1(r_2+r_3)}{X_0}+\frac{r_2r_3}{X_0}\frac{(X_m+x_1)}{(X_m+x_2)}+S(r_3-r_2)K_r\sin A\cos A-(1-S^2)\left[\frac{x_1X_m+x_2X_m+x_1x_2}{X_m+x_2}\right]$$

$$\Phi_{f\max}=I_2X_0\left(\frac{I_1}{I_2}K_p\sin A-1\right)\frac{45\times10^6}{fCK_w}$$

$$\Phi_{t\max}=I_3X_0\left(\frac{I_1}{I_3}K_p\cos A-1\right)\frac{45\times10^6}{fCK_w}$$

(It must be remembered that the currents are vectors in these equations.)

Let us now define

$$i_m=\frac{E}{X_0}$$

$$X=x_1+x_2K_p=\frac{x_1X_m+x_2X_m+x_1x_2}{X_m+x_2}$$

Then

$$I_1=\frac{i_mr_2\dfrac{r_3}{X_0}-E(1-S^2)+ji_m(r_2+r_3)}{U+jW}$$

$$I_2=\frac{-Si_mr_3K_p\sin A-(1-S^2)EK_p\cos A+ji_mr_3K_p\cos A}{U+jW}$$

$$I_3=\frac{Si_mr_3K_p\cos A-(1-S^2)EK_p\sin A+ji_mr_3K_p\sin A}{U+jW}$$

The torque equation is not affected by these last simplifications.

$$U=-(1-S^2)r_1-r_2K_r\cos^2 A-r_3K_r\sin^2 A-\frac{r_2+r_3}{X_0}X+\frac{r_1r_2r_3}{X_0^2}$$

$$W=-(1-S^2)X+S(r_3-r_2)K_r\sin A\cos A+r_1\frac{r_2+r_3}{X_0}+\frac{r_2r_3(X_m+x_1)}{X_0(X_m+x_2)}$$

In motors of normal proportions, r_3 is very large, and often as a check, a calculation is made with r_3 increased to infinity. This is a convenient way to tell whether the brush resistance is as large as it ought to be. Let us divide both numerator and denominator of the current equations by $-r_3$ and the torque equation by $(-r_3)^2$. This will cause the terms affected by the useless brush short-circuit current, to become smaller and smaller as r_3 approaches infinity.

$$U=(1-S^2)\frac{r_1}{r_3}+\frac{r_2}{r_3}K_r\cos^2 A+K_r\sin^2 A+\frac{X}{X_0}\left(1+\frac{r_2}{r_3}\right)-\frac{r_1r_2}{X_0X_0}$$

$$W=(1-S^2)\frac{X}{r_3}-S\left(1-\frac{r_2}{r_3}\right)K_r\sin A\cos A-\frac{r_1}{X_0}\left(1+\frac{r_2}{r_3}\right)-\frac{r_2}{X_0}\frac{(X_m+x_1)}{(X_m+x_2)}$$

$$I_1=\frac{(1-S^2)\dfrac{E}{r_3}-\dfrac{i_mr_2}{X_0}-ji_m\left(1+\dfrac{r_2}{r_3}\right)}{U+jW}$$

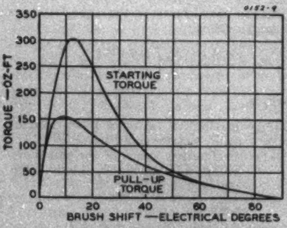

Figure 9. Effect of brush shift on starting and pull-up torques

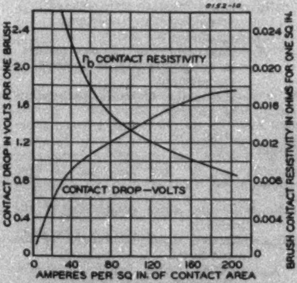

Figure 10. Typical brush resistance and volt-ampere curves

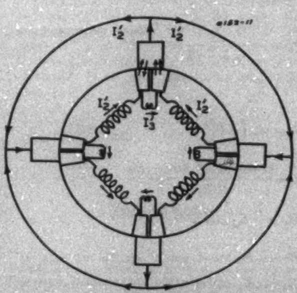

Figure 11. Schematic diagram of secondary circuit of repulsion motor

$$I_2=\frac{(1-S^2)\dfrac{E}{r_3}K_p\cos A+Si_mK_p\sin A-ji_mK_p\cos A}{U+jW}$$

$$I_3=\frac{(1-S^2)\dfrac{E}{r_3}K_p\sin A-Si_m\dfrac{r_2}{r_3}K_p\cos A-ji_m\dfrac{r_2}{r_3}K_p\sin A}{U+jW}$$

$$T=\frac{S\left\{(1-S^2)\left[\dfrac{\overline{EK_p}^2}{r_3}\left(\dfrac{r_2}{r_3}\cos^2 A+\sin^2 A\right)\right]-\left(\dfrac{EK_p}{X_0}\right)^2 r_2\left(\dfrac{r_2}{r_3}\cos^2 A+\sin^2 A\right)\right\}}{U^2+W^2}+\frac{\dfrac{\overline{EK_p}^2}{X_0}\sin A\cos A\left[1-\left(\dfrac{r_2}{r_3}\right)^2\right]}{U^2+W^2}$$

For purposes of calculation, let us arrange the terms in each equation into groups, those terms which are a function of speed in one group, and those which are independent of speed in another group.

$$U=(1-S^2)\frac{r_1}{r_3}+H_2$$

where

$$H_2=K_rB+\frac{X}{X_0}\left(1+\frac{r_2}{r_3}\right)-\frac{r_1r_2}{X_0X_0}$$

(This last term $\frac{r_1r_2}{X_0X_0}$ is usually negligible)

$$B=\frac{r_2}{r_3}\cos^2 A+\sin^2 A$$

$$W=(1-S^2)\frac{X}{r_3}-SH-H_1$$

$$H_3=K_r\left(1-\frac{r_2}{r_3}\right)C$$

$$C=\sin A\cos A$$

$$H_1=\frac{r_1}{X_0}\left(1+\frac{r_2}{r_3}\right)+\frac{r_2}{X_0}\frac{(X_m+x_1)}{(X_m+x_2)}$$

(The term $\frac{(X_m+x_1)}{(X_m+x_2)}$ can usually be taken as unity)

$$I_1=\frac{(1-S^2)\dfrac{E}{r_3}-H_4-jH_{10}}{U+jW}$$

$$H_4=\frac{i_mr_2}{X_0}$$

$$H_{10}=i_m\left(1+\frac{r_2}{r_3}\right)$$

$$I_2=\frac{(1-S^2)H_{12}+SH_8-jH_9}{U+jW}$$

$$H_{12}=\frac{E}{r_3}K_p\cos A$$

$$H_8=i_mK_p\sin A$$

$$H_9=i_mK_p\cos A$$

$$I_3=\frac{(1-S^2)H_{13}-SH_5-jH_6}{U+jW}$$

$$H_{13}=\frac{E}{r_3}K_p\sin A$$

$$H_5=i_m\frac{r_2}{r_3}K_p\cos A$$

$$H_6=i_m\frac{r_2}{r_3}K_p\sin A$$

Torque in synchronous watts =

$$\frac{S[(1-S^2)H_{14}-H_7]+H_{11}}{U^2+W^2}$$

$$H_7=i_m^2r_2K_rB$$

$$H_{11}=EH_{10}H_8$$

$$H_{14}=\overline{EK_p}^2\frac{B}{r_3}$$

Output = S times torque in synchronous watts

Torque in ounce-feet = $\frac{112.7}{\text{synchronous rpm}}$ times torque in synchronous watts

By arranging the calculation of these terms in proper sequence, a simple and straightforward calculation sheet may be obtained. Such a calculation sheet is shown in figure 12.

Appendix II

Derivation of the Equations of Rotor Resistance

The secondary resistance of the armature of a repulsion motor must be calculated for two separate conditions when operating repulsion, and for a third condition when operating induction in a repulsion-start, induction-run motor. In all cases, the problem is to obtain the effective secondary resistance, referred to the primary, of a motor which for this problem may be considered as a transformer. Since the resistances of a transformer may be transferred from primary to secondary or vice versa by multiplying by the square of the transformation ratio, the problem becomes one of correctly determining the actual secondary resistance, and the transformation ratio.

Let

"ratio" = transformation ratio squared
r_s = actual secondary resistance
r_c = resistance per coil
N_c = total number of coils on armature
r_2 = secondary resistance referred to the primary
a = the number of parallel paths in the secondary

$$\text{"ratio"}=\frac{(CK_{wm})^2}{(CK_{ws})^2}$$

where

CK_{wm} = effective series conductors of the primary
CK_{ws} = effective series conductors of the secondary
K_w = winding factor (pitch times distribution factor)

Then

r_2 = "ratio" times r_s

CASE I

Repulsion-start, induction-run motor operating induction with all bars of the commutator short-circuited.

$r_{s1}=r_c/N_c$
$CK_{ws}=2\,tpc\,K_{ws1}$ (K_{ws1} is usually close to 0.637)
tpc = turns per coil on the armature

CASE II

Normal repulsion motor, r_2 = resistance of main phase or useful part of the armature.

$$r_{s2}=\frac{\dfrac{r_cN_c}{a}+\dfrac{r_b4}{A_b}}{a}$$

where

N_c/a = number of coils between brushes
r_b = resistance per square inch of brush contact
A_b = brush contact area in square inches (minus that area of the brush in contact with mica)
$CK_{ws2}=\dfrac{2\,tpc\,N_cK_{ws2}}{a}$ (K_{ws2} is usually close to 0.637)

It can be shown that if r_b equal zero, $r_{s1}=r_{s2}$. Thus

$$r_2=r_{s1}\frac{R_A+R_B}{R_A}$$

Where

$$R_A=\frac{r_cN_c}{a}\text{ and }R_B=\frac{r_b4}{A_b}$$

CASE III

Normal repulsion motor, r_3 = secondary resistance of the short-circuited coils.

$$r_{s3}=\frac{r_c+\dfrac{r_b4}{A_b}}{a}$$

$CK_{ws3}=2\,tpc\,K_{ws3}$ (K_{ws3} is usually equal to the armature chord factor, for with the brush spanning two bars only, and the one coil connected to these bars in one slot only, the distribution factor will be unity)

A convenient method calculating r_3 is to write the formula in terms of r_{s1}

$$r_3=r_{s1}\frac{(K_{ws1})^2}{(K_{ws3})^2}\frac{r_c+R_B}{r_c}\frac{N_c}{a}$$

But the chord factor is the same for either case, therefore

$$r_3=r_{s1}\left\{\frac{r_c+R_B}{r_c}\frac{N_c}{a}\left[\frac{DF_{s1}}{DF_3}\right]^2\right\}$$

where

DF_{s1} = distribution factor of short-circuited rotor, usually about 0.637
DF_3 = distribution factor of the coil short-circuited by the brush, usually unity

$$DF=\frac{\sin n\theta/2}{n\sin\theta/2}$$

where

n = number of coils
θ = angle between coils in electrical degrees

Performance Calculations on Capacitor Motors

The Revolving-Field Theory

P. H. TRICKEY
MEMBER AIEE

Synopsis: A method is presented whereby the equations of capacitor motor performance calculation as developed by Mr. W. J. Morrill,[1] are arranged in a calculation sheet or form for use in routine design work.

IN 1929, W. J. Morrill presented his classic paper on "The Revolving Field Theory of the Capacitor Motor", giving the complete equations for calculating the performance and torque of a capacitor motor at any value of slip.

The equations are straightforward, but involve vector operations, and are rather slow for routine design work. Since 1929, many engineers have used the method, and have devised different methods of doing the many numerical operations necessary to obtain a final solution. The methods have varied from one extreme to the other, some engineers using the equations directly as written making each vector operation as necessary, and others working up a calculation sheet where all operations were numerical.

Although engineers as a rule are perfectly capable of handling vector operations, most of those involved in motor design work, feel that any great number of vector operations in the midst of routine work, brings considerable risk of errors, and they like to avoid vectors where possible. The writer has developed a calculation sheet for using these formulas, where all the operations except the last in calculating the currents are performed without vectors. This seems to be a fairly satisfactory compromise between the difficulties of either extreme, and has worked out quite well in practice.

Calculation Sheet for Mr. Morrill's Equations

Figures 1 and 2 show pages 1 and 2 of the calculation method. As in Mr. Morrill's paper, the method consists of determining the currents in each branch circuit and their angles with the voltage. With these values, the torque, output, and losses may be determined. Figure 1 is taken up with the calculation of currents, and figure 2 with calculation of torque and performance. The first part of figure 1 covers the calculation of the apparent resistance and reactance of the secondary circuit to the forward and backward fields.

It will be noted that many of the terms and expressions in the equations are of very similar form. Advantage has been taken of this to arrange the sheet so that the operations are performed in two columns in such a way that the numbering of the operations is nearly the same. That is, operations 1, 2, 3, 4, etc. are exactly the same in form as operations 101, 102, 103, and 104. Upon reaching operation 13 and 113, it becomes necessary to cross from one column to the other occasionally, but the same essential similarity between the two columns is kept.

Iron Loss

A slightly different method of accounting for iron loss is used than that of Mr. Morrill. Mr. Morrill's equations neglect iron loss and then correct for it by adding it to the friction and windage losses as a reduction in output.

The writer has found that a closer comparison between calculated values and tested values may be obtained, if a slightly different method of iron loss correction is used. As with Mr. Morrill, the vector operations of items 35, and 37 give fictitious values of current which have been obtained while neglecting iron loss entirely. These fictitious values are used in calculating the internal torque and output. The friction, windage, and odd-frequency iron losses are then sub-

Paper 40-153, recommended by the AIEE committee on electrical machinery, and presented at the AIEE Middle Eastern District meeting, Cincinnati, Ohio, October 9–11, 1940. Manuscript submitted May 2, 1939; made available for preprinting September 4, 1940.

P. H. Trickey is section head, fractional-horsepower motor design, Diehl Manufacturing Company, Elizabethport, N. J.

Brush Contact Resistance

The equations for secondary resistance contain a term which is a function of the contact drop at the brush and commutator. The resistance of the contact is determined by a number of things. First, the type of brush, second the current density, and in addition to these factors it is affected by the speed and temperature of the commutator. A typical brush resistance curve as a function of current density is shown in figure 10. It is furnished through the courtesy of the National Carbon Company. It will be noted that the curve has been extended beyond the conditions of normal continuous operation. This is done because motors designed for repulsion operation during the starting period only, have small brushes, and abnormally high current densities. These densities are likely to be between 100 and 300 amperes per square inch at the standstill condition.

As mentioned above, in order to be exact, it would be necessary to use a different value of brush resistance for each point of a calculated speed-torque curve. However, for practical cases, it is usually sufficiently accurate, to use the starting current density throughout the entire range of the caclulation.

Actual Secondary Currents

Figure 11 illustrates the conditions occurring at the brush, with the useful currents entering the brush from adjacent commutator bars, and the short-circuit current entering from one bar and leaving by way of the next bar. It may happen in some cases, that the short-circuit current is even greater than the useful current. For convenience, the actual values of the currents are given below.

$$I_2' = I_2 \frac{CK_{wm}}{CK_{w2}} \frac{1}{a}$$

$$I_3' = I_3 \frac{CK_{wm}}{CK_{w3}} \frac{1}{a}$$

Reactance Voltage

Since r_3 is so much greater than the reactance of the short-circuited coils, the commutation voltage referred to the primary is simply $I_3 r_3$. However, the actual voltage commutated by the brush must be obtained from the transformation ratio, that is,

$$E_c = I_3 r_3 \frac{2tpcK_{w3}a}{CK_{wm}}$$

Figure 2. Calculation sheet for capacitor motors, page 2

tracted to give the useful output. A close approximation to the true current is obtained by adding to the in-phase component of the main winding current a value of in-phase current obtained by dividing the fundamental-frequency iron loss by the voltage.

This method accounting for the iron loss is based on the fact that the fundamental-frequency iron losses are normally supplied by the stator and the odd-frequency losses of the surfaces and tooth pulsations are supplied by the rotating member with a corresponding loss of torque.

Performance Calculation

Credit should be given to C. G. Veinott of the Westinghouse Electric and Manufacturing Company for the essential form of figure 2. It should be noted that the fictitious values of the currents are used for calculating the torque and the corrected values for calculating the stator copper losses. The odd-frequency iron losses are subtracted from the gross output along with the friction and windage.

It is believed that more accuracy is secured by obtaining the input from the output plus losses rather than by multiplying the voltage and the in-phase component of the line current. However, it is usually wise to check the two methods against each other.

Appendix

It is well at this point to definitely state the object of the following derivations. It is simply this: Starting with Mr. Morrill's equations, the object is to develop a simple routine calculation form which will give the performance of a capacitor motor at any speed when the necessary impedances or motor constants are known. The desired form is one with which results of practical accuracy are obtained with a minimum amount of calculation time, and the least likelihood of errors. From the point of view of routine work, it is also desirable that the work may be easily resumed after interruptions such as telephone calls, interviews, etc.

Since the design engineer who works on single-phase motors is very likely to design split-phase, capacitor-start, repulsion, and capacitor-run motors, the symbols and form of the calculation sheet have been arranged in accordance with the single-phase performance method of C. G. Veinott[2] and with the repulsion motor method of the writer now in process of publication by the AIEE.

The three fundamental equations of Mr. Morrill are as follows:

$$I_m=E_m\left\{\frac{[R_c+a^2(R_{1a}+R_f+R_b)]+j[X_c+a^2(X_{1a}+X_f+X_b)]+ja[(R_f-R_b)+j(X_f-X_b)]}{\{[R_c+a^2(R_{1a}+R_f+R_b)]+j[X_c+a^2(X_{1a}+X_f+X_b)]\}\{(R_{1m}+R_f+R_b)+j(X_{1m}+X_f+X_b)\}-a^2[(R_f-R_b)+j(X_f-X_b)]^2}\right\} \qquad (122)$$

$$I_s=E_m\left\{\frac{[(R_{1m}+R_f+R_b)+j(X_{1m}+X_f+X_b)]-ja[(R_f-R_b)+j(X_f-X_b)]}{\{[R_c+a^2(R_{1a}+R_f+R_b)]+j[X_c+a^2(X_{1a}+X_f+X_b)]\}\{(R_{1m}+R_f+R_b)+j(X_{1m}+X_f+X_b)\}-a^2[(R_f-R_b)+j(X_f-X_b)]^2}\right\} \qquad (123)$$

$$\text{Torque(average)}=[I_m{}^2+a^2I_s{}^2][R_f-R_b]+2a[Ah-Bg][R_f+R_b] \qquad (8)$$

where

$I_m=A+jB$ and $I_s=g+jh$

The rearrangement consists of the steps:

A. Rewriting the equations in the symbols of Mr. Veinott's paper.

B. Rewriting the equations for the forward and backward impedances.

C. Obtaining the current terms $A+jB$ and $g+jh$ in quotient form.

$$A+jB=\frac{(26)+j(126)}{(33)+j(133)}$$

and

$$g+jh=\frac{(20)+j(120)}{(33)+j(133)}$$

D. Rearranging the torque equation so that the components $(26)+j(126)$ and $(20)+j(120)$ may be used instead of $A+jB$ and $g+jh$. This allows the calculation of torque without any vector operations.

E. Adding an in-phase iron loss component to $A+jB$ to correct for stator iron loss.

F. Addition of phase currents to obtain the line current.

A. REWRITING THE EQUATIONS IN THE SYMBOLS OF MR. VEINOTT'S PAPER. (SEE TABLE I)

Let us arbitrarily define

$$X_0=X_m+x_2,\quad K_p=X_m/(X_m+x_2),\quad K_r=K_p{}^2=X_m{}^2/X_0{}^2$$

Substitute these values and divide both numerator and denominator by $X_0^2/4$

$$R_f=\frac{1}{2}\,\frac{(r_2K_r)1/s}{[(r_2/X_0)(1/s)]^2+1}$$

R_b becomes the same equation with $(2-s)$ in place of s

$$R_b=\frac{1}{2}\,\frac{(r_2K_r)\,1/(2-s)}{[(r_2/X_0)(1/(2-s))]^2+1}$$

Mr. Morrill writes

$$X_f=\frac{X_m[(R_2/s)^2+X_2(X_2+X_m)]}{(R_2/s)^2+(X_2+X_m)^2}=$$

Rewritten in symbols of Mr. Veinott

$$\frac{(X_m/2)[(r_2/2s)^2+x_2(x_2+X_m)/4]}{(r_2/2s)^2+(x_2+X_m)^2/4}$$

Table I

New Symbol	Old Symbol	Definition
K	a	$\dfrac{\text{Total effective series conductors in auxiliary phase}}{\text{Total effective series conductors in main phase}}$
r_{1a}	a^2R_{1a}	Primary resistance of auxiliary phase
x_{1a}	a^2X_{1a}	Primary leakage reactance of auxiliary phase
r_{1m}	R_{1m}	Primary resistance of main phase
r_2	$2R_2$	Total secondary resistance referred to primary of main phase
x_{1m}	X_{1m}	Primary leakage reactance of main phase
x_2	$2X_2$	Total secondary leakage reactance referred to primary of main phase
X_m	$2X_m$	Total magnetizing reactance of main phase
s	S	Slip in per unit of synchronism
I_a	I_s	Auxiliary phase current

$$I_m=E_m\left\{\frac{[R_c+r_{1a}+K^2(R_f+R_b)]+j[X_c+x_{1a}+K^2(X_f+X_b)]+jK[(R_f-R_b)+j(X_f-X_b)]}{\{[R_c+r_{1a}+K^2(R_f+R_b)]+j[X_c+x_{1a}+K^2(X_f+X_b)]\}\{(r_{1m}+R_f+R_b)+j(x_{1m}+X_f+X_b)\}-K^2[(R_f-R_b)+j(X_f-X_b)]^2}\right\}$$

$$I_a=E_m\left\{\frac{[(r_{1m}+R_f+R_b)+j(x_{1m}+X_f+X_b)]-jK[(R_f-R_b)+j(X_f-X_b)]}{\{[R_c+r_{1a}+K^2(R_f+R_b)]+j[X_c+x_{1a}+K^2(X_f+X_b)]\}\{(r_{1m}+R_f+R_b)+j(x_{1m}+X_f+X_b)\}-K^2[(R_f-R_b)+j(X_f-X_b)]^2}\right\}$$

$$T_{\text{avg}}=(I_m{}^2+K^2I_a{}^2)(R_f-R_b)+2K(Ah-Bg)(R_f+R_b)$$

B. REWRITING THE FORWARD AND BACKWARD IMPEDANCES

Mr. Morrill's equation

$$R_f=\frac{X_m{}^2\,R_2/s}{(R_2/s)^2+(X_2+X_m)^2}=$$

Rewritten in symbols of Mr. Veinott

$$\frac{(X_m/2)^2\,(r_2/2)(1/s)}{(r_2/2)^2(1/s)^2+\left(\dfrac{x_2+X_m}{2}\right)^2}$$

Substitute $X_0=X_m+x_2$, $K_p=X_m/(X_m+x_2)$, divide both numerator and denominator by $X_0/4$, and rearrange

$$X_f=\frac{1}{2}\,\frac{x_2K_p+(r_2K_p)(r_2/X_0)(1/s)^2}{[(r_2/X_0)(1/s)]^2+1}$$

and

$$X_b=\frac{1}{2}\,\frac{x_2K_p+(r_2K_p)(r_2/X_0)(1/(2-s))^2}{[(r_2/X_0)(1/(2-s))]^2+1}$$

C. OBTAINING A+jB AND g+jh IN QUOTIENT FORM

It will be noted from the equations of I_m and I_a, that many of the groups of terms are the same. Let us rewrite them using a symbol for each group. For simplicity let us use for symbols the item numbers of the final calculation sheets figures 1 and 2. Our purpose is to obtain

$$A+jB=\frac{(26)+j(126)}{(33)+j(133)}$$

and

$$g+jh=\frac{(20)+j(120)}{(33)+j(133)}$$

Then, assigning a number symbol to each term, we obtain

$$A+jB=E_m\times\left\{\frac{(24)+j(124)+jK[(15)+j(115)]}{\{(24)+j(124)\}\{(18)+j(118)\}-K^2[(15)+j(115)]^2}\right\}$$

$$g+jh=E_m\times\left\{\frac{(18)+j(118)-jK[(15)+j(115)]}{\{(24)+j(124)\}\{(18)+j(118)\}-K^2[(15)+j(115)]^2}\right\}$$

Simplifying to obtain one real and one quadrature term in both numerator and denominator,

$$A+jB=E_m\times\left\{\frac{[(24)-K(115)]+j[(124)+K(15)]}{[(24)(18)-(124)(118)-K^2(15)^2+K^2(115)^2]+j[(18)(124)+(118)(24)-2(K15)(K115)]}\right\}$$

$$g+jh=E_m\times\left\{\frac{[(18)+K(115)]+j[(118)-K(15)]}{[(24)(18)-(124)(118)-K^2(15)^2+K^2(115)^2]+j[(18)(124)+(118)(24)-2(K15)(K115)]}\right\}$$

Assigning number symbols to the above groups of terms,

$$A+jB=E_m\frac{(26)+j(126)}{(32)+j(132)}$$

and

$$g+jh=E_m\frac{(20)+j(120)}{(32)+j(132)}$$

Dividing numerator and denominator by E_m gives the desired result

$$A+jB=\frac{(26)+j(126)}{(33)+j(133)}$$

and

$$g+jh=\frac{(20)+j(120)}{(33)+j(133)}$$

D. REARRANGING THE TORQUE EQUATION

$$T=(I_m^2+K^2I_a^2)(R_f-R_b)+2K(Ah-Bg)(R_f+R_b)$$

In order to avoid making the vector operation involved in obtaining A, B, g, and h, let

$$N_m=\sqrt{(26)^2+(126)^2}$$

$$N_a=\sqrt{(20)^2+(120)^2}$$

$$V=\sqrt{(33)^2+(133)^2}$$

Also since $(Ah-Bg)$ is the quadrature term obtained by multiplying $(g+jh)$ by the conjugate of $(A+jB)$, performing this operation on both right and left sides of the equations gives us an expression for $(Ah-Bg)$.

$$(A-jB)(g+jh)=(Ag+Bh)+j(Ah-Bg)$$

$$\frac{(26)-j(126)}{(33)+j(133)}\times\frac{(20)+j(120)}{(33)+j(133)}=\frac{[(26)(20)+(126)(120)]-j[(26)(120)-(126)(20)]}{(33)^2+(133)^2}$$

Thus

$$Ah-Bg=\frac{(26)(120)-(126)(20)}{V^2}$$

and

$$T=[(N_m/V)^2+(KN_a/V)^2](R_f-R_b)+2K\left[\frac{(26)(120)-(126)(20)}{V^2}\right](R_f+R_b)$$

This allows the calculation of torque without any vector operations, which is particularly desirable in calculating speed-torque curves, pull-up torque of capacitor-start motors, or in designing two- or three-speed fan motors.

E. CORRECTING FOR PRIMARY IRON LOSS

Although the fundamental frequency iron loss is supplied by the primary, and the odd-frequency iron loss by the rotor, it is not possible to include the stator iron loss in the primary part of the revolving field equations without making them too complicated. If the total iron loss is subtracted from the output similar to the friction and windage losses, it will be found in certain motors, particularly those designed for speed change driving low-horsepower fans, that the calculated useful torque will not agree with the tested value. The writer has had considerable success in approximating the true condition by simply adding an in-phase current component to the main phase current to account for the stator iron loss. This seems to agree with test much closer than adding half to the main phase and half to the auxiliary phase. The final main phase current is then

$$A+\frac{\text{fundamental-frequency iron loss}}{E_m}+jB$$

The auxiliary phase current is $g+jh$, and the line current is the vector sum.

In figure 1 the fundamental-frequency iron loss is denoted by the symbol "60 Cy Fe" and the odd-frequency iron loss by the symbol "Hi Cy Fe". $F+W$ is used as the symbol for friction and windage.

As a matter of interest, the motor used as an example for figure 1 is a one-fourth horsepower 230-volt 60-cycle six-pole single-value capacitor motor designed for three-speed unit-heater fan service to be used with an autotransformer for speed control.

Synopsis: Increasing concentration of power combined with the desire for more compact switchgear assemblies has created a demand for small, totally enclosed, high-interrupting-capacity fuses suitable for potential and operating transformer protection. The current-limiting fuse meets these requirements for it is inherently a high-interrupting-capacity fuse of low current rating and can be totally enclosed in a small space.

The theory and construction of previous current-limiting fuses are briefly described. The theory and construction of a new current-limiting fuse is given. The new fuse is simple in theory and construction. Its fundamental elements can be separated, studied, and tested, making it possible to predict an unusual degree of reliability and freedom from voltage surges. Test results confirm the reliability, high interrupting capacity, and freedom from voltage surges of the new fuse.

THE development and adoption of the first current-limiting fuses were prompted by the need for high interrupting ability. The other characteristics of the fuse were merely incidental and were not major factors in the wide acceptance of the current-limiting fuse in Europe. To limit the current and thereby limit the amount of energy liberated in the fuse was one way of obtaining high interrupting ability. In fact, before the advent of boric acid, as an interrupting medium, the current-limiting fuse was the only fuse that could safely be applied to many of the systems then in existence. During 1931 current-limiting fuses were imported, tested, and studied for possible adoption in this country where high interrupting ability was required. These fuses had the desirable features of high interrupting ability in a relatively small size and did not expel arc gases or other material during operation. However, the limited range of current ratings available in the fuse so restricted the scope of its application that its commercial development for use in this country was abandoned. Further development evolved the boric acid fuse with its high interrupting ability, totally enclosed features, and wide range of current ratings.

The increased use of metal-enclosed switchgear has placed a premium on space. The amount of room required for a low-interrupting-ability fuse with current-limiting resistor or a standard power fuse for the protection of potential or small operating transformers appears to be all out of proportion to the size of the apparatus being protected and the load handled. It should be remembered, however, that the real duty of the fuse is to protect the system rather than the apparatus. There is a need, therefore, for a fuse having the small size and characteristics of the current-limiting fuse for connecting small loads to high-power systems as a supplement to power fuses that are used for heavier capacity loads.

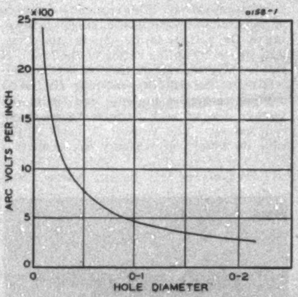

Figure 1. Characteristics of arcs in small holes

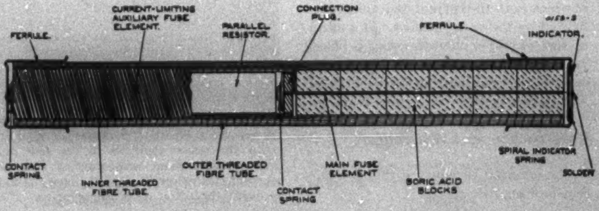
At the present time there are two types of current-limiting fuses available. One type consists of a fuse and resistor in series enclosed in a common cartridge. The resistor limits the current during the interruption of the fuse. The required characteristics of a resistor to carry load current and to limit the current on short circuit are directly opposed. To satisfactorily combine both characteristics in one resistor requires a relatively large resistor that necessitates a bulky cartridge.

The other type of current-limiting fuse consists of a silver wire spirally wound on a ceramic core and surrounded by inert crystals.[1,4] This type of fuse has had an excellent record in Europe for over a decade and in this country for two years. Characteristics of this fuse believed capable of improvement are:

1. It has a high melting temperature and, therefore, if made in higher ampere ratings would have a high operating temperature.
2. It offers no flexibility in obtaining time-current characteristics to meet various applications.
3. On operations at currents slightly above the melting point of the wire the operation may not be as reliable as in a spring-operated fuse.
4. The reliability of the fuse depends on the characteristics of the inert crystals used, therefore, a reliable source of supply and very rigid inspection are necessary to maintain the quality of the fuse.

Early tests on various forms of current-limiting fuses revealed high voltage surges during current limitation. Small variations in construction would result in widely different surge voltages. In order for a fuse to limit the current a voltage must be produced in the fuse equal to or greater than the voltage available in the circuit at the time of current limitation. Also the voltage produced must not rise to a value that might cause flashover or otherwise endanger the circuit on which it is applied. It is evident, therefore, that in order for a current-limiting fuse to be

Figure 2. Sectional view of new-type current-limiting fuse



Paper 40-188, recommended by the AIEE committee on protective devices, and presented at the AIEE Middle Eastern District meeting, Cincinnati, Ohio, October 9–11, 1940. Manuscript submitted August 13, 1940; made available for preprinting August 26, 1940.

STROM is research engineer in the high-voltage laboratory of the company at Trafford, Pa., and H. W. GRAYBILL is design engineer in the switchgear engineering department of the company at East Pittsburgh.

1. For all numbered references, see list at end of paper.

reliable the voltage rise during current limitation must be accurately controlled and kept within a definite range. A further requirement of reliability is that the means for controlling the voltage rise should not be critical or susceptible to the small variations in size or material that are liable to occur in commercial production.

Investigations on arcing characteristics revealed that arcs drawn in small holes in solid material gave a high arc voltage that increased very rapidly as the size of the hole was reduced.[3] This characteristic is shown by the curve in figure 1. By utilizing a very small hole, a very high arc voltage and therefore a very definite current-limiting action can be obtained. The smaller the hole, the higher the arc voltage and the more reliable the current-limiting action will be, disregarding any possible danger to the system from the high voltage.

Figure 3. Photograph of new current-limiting fuse

To limit the voltage on any device it is merely necessary to by-pass the current through a suitable resistor. This resistor may have a valve characteristic to limit the current at normal voltage and permit much higher currents to flow at higher voltages. If the fuse wire in a very small bore is paralleled with such a resistor, the basis is formed for a current-limiting fuse with a very definite and reliable current-limiting element and a very definite and reliable voltage-limiting element. A greater degree of reliability can be attained in such a device than in a device in which both the current and voltage are limited by the same element. If a clean-up fuse of proper characteristics is placed in series with such a combination, a complete current-limiting fuse is obtained. Such a fuse is shown in figures 2 and 3.

Construction and Operation

The essential elements of this new current-limiting fuse are:

1. *The Auxiliary or Current-Limiting Fuse Element.* This consists of a silver wire spirally wound on a multipitch threaded fiber tube which is screwed into a similarly threaded tube that forms the outer shell of the fuse holder. Fiber was selected for this purpose due to its gas-evolving properties and its mechanical strength although numerous tests have not demonstrated the need for any great mechanical strength in these parts. With gas-evolving material around the fuse element the arc voltage will be higher than with nongas-evolving materials. Furthermore, residual arc currents will be interrupted quickly with no possibility of a low-resistance path due to incandescent surfaces. The clearance left in the bottom of the thread after assembly provides a small hole slightly larger than the diameter of the wire, in which arc restriction occurs. On assembly a special cement is applied to the threads to form a seal between threads. Even with loose fitting parts the arc voltage produced in the restricted hole is many times the voltage required for current transfer to the parallel resistor rod.

2. *The Parallel Resistor Rod or Voltage-Limiting Element.* This element is a silicon-carbide rod of proper characteristics depending on the voltage rating, the current rating, and the interrupting rating of the fuse. It has a valve characteristic that becomes effective at currents approaching the interrupting rating of the fuse and limits the voltage rise at such currents to relatively safe values. This resistor is inside of the tube on which the auxiliary fuse element is wound. Connection is made to it by means of contact springs. No special precautions are necessary in making contact with the resistor, as it passes current only during arc interruption, when full line voltage is impressed across the fuse.

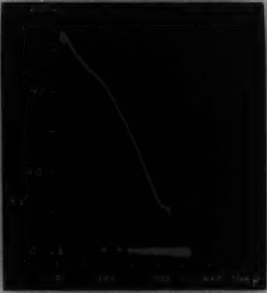


Figure 4. Dynamic volt-ampere characteristic of auxiliary fuse on 500-ampere 10x100-microsecond current wave

3. *The Main Fuse Element.* This element, the clean-up element, is connected in series with the other elements of the fuse and serves as the final interrupter of all overcurrents that flow through the fuse. It also provides isolation after interruption. The fuse element operates in a small hole through solid boric acid. The excellent performance of boric acid in fuses both on low and high currents has been described in previous publications and has been demonstrated by many years in commercial use.[2] In the new current-limiting fuse this interrupting element is subjected to very easy service since it is called upon to open either extremely low currents or moderately low currents at a high power factor. The main fuse element itself is of the low-temperature type, can be designed to give any desired time-current characteristics, and is spring operated to insure a positive gap on low-current operations. The spring that separates the fuse element also operates a suitable indicator that provides visual indication of a blown fuse.

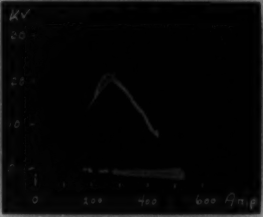

Figure 5. Dynamic volt-ampere characteristic of auxiliary fuse with parallel resistor rod on 500-ampere 10x100-microsecond current wave

The action of the fuse on low currents is not the same as on high currents due to the main fuse element being calibrated to melt at a lower current than the auxiliary fuse element. This was done to prevent any appreciable temperature rise of the auxiliary silver fuse wire and eliminate the possibility of the auxiliary fuse being melted before the main fuse. On low values of current the main fuse element may melt and interrupt the current without the auxiliary fuse wire being melted. In a fuse designed for potential-transformer protection this will happen on all currents below approximately 80 amperes. On high-current operation, the auxiliary fuse will melt on the initial rise in current and transfer the current to the parallel resistor rod. The thermal capacity of this rod is sufficient to permit a half cycle of current to pass through it without an excessive temperature rise. At the end of the first half cycle after current transfer the main fuse will interrupt the circuit.

Theory and Calculations

The operating characteristics of the current and voltage-limiting elements of this fuse are of particular importance. Calculations can readily be made from which the performance of the device may be predicted.

When a short circuit occurs the current rises in the auxiliary fuse element with practically no limiting influence until the fuse element melts. At this point voltage rises rapidly to a high arc voltage and the current is limited and transferred to the resistor rod.

The maximum value which the current may reach when the fuse melts may be readily computed. Since the temperature rise of the fuse wire equals

$$\frac{\text{energy input}}{\text{mass} \times \text{specific heat}}$$

an infinitesimal temperature rise,

$$dT = \frac{i^2R(1+aT)dt}{Mk} \tag{1}$$

where

T = temperature, degrees centigrade
i = amperes
t = seconds
R = fuse resistance at zero degrees
a = temperature coefficient of resistance
M = mass of fuse wire, grams
k = watt seconds per gram per degree centigrade

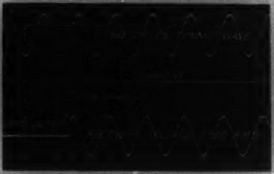

Figure 6. Operation of current-limiting fuse on a 2.3-kv system, with 20,000-ampere available short-circuit capacity

The maximum rate of current rise occurs on symmetrical short circuits. Under such conditions we may, for simplicity and without appreciable error, assume that the current in the fuse wire up to the melting point is linear and equal to:

$$i = 377I_mt \tag{2}$$

where I_m = maximum value of available 60-cycle short-circuit current.

We may then rewrite equation 1 as follows:

$$\frac{dT}{R(1+aT)} = \frac{(377)^2I_m^2}{Mk}t^2dt \tag{3}$$

Integrating equation 3, taking T between the limits of the initial fuse temperature, T_i, and the melting temperature, T_m, gives:

$$\frac{1}{Ra}\log_e\frac{1+aT_m}{1+aT_i} = \frac{(377)^2I_m^2}{Mk}\frac{t_m^3}{3} \tag{4}$$

whence time to the melting point,

$$t_m = \sqrt[3]{377I_m \cdot \frac{3Mk}{Ra}\log_e\frac{1+aT_m}{1+aT_i}} \tag{5}$$

Substituting this value of t in equation 2, gives the current at time of melting.

$$i_m = \sqrt[3]{377\,I_m \cdot \frac{3Mk}{Ra}\log_e\frac{1+aT_m}{1+aT_i}} \tag{6}$$

Whence

$$i_m = K\sqrt[3]{I_m}$$

This indicates that as the available system short-circuit current rises, the maximum value of the initial rush of short-circuit current in the fuse increases only as the cube root of the available short-circuit current. Thus, if the available short circuit increases from 10,000 to 80,000 amperes, the maximum value to which current can rise in the fuse will only double.

This is important since the initial voltage surge caused by the blowing of the fuse cannot exceed the product of the maximum initial fusing current times the resistance of the parallel resistor rod. It is, therefore, possible to design this fuse so as not to exceed any specified surge voltage. Since ordinary switching operations frequently cause voltage surges of twice the peak system voltage it is evident that the fuse may safely be designed to have twice peak value as an upper limit of surge voltage when the parallel fuse melts. Thus, if the fuse is designed to give a maximum surge voltage on a 10,000-ampere system, equal to peak voltage, then, since the surge varies as the cube root of the available system current, a short circuit on an 80,000-ampere system can be interrupted without exceeding a surge of twice the peak voltage. This indicates that a fuse of this type can cover a wide range of short-circuit currents without subjecting connected apparatus to excessive voltage surges.

As previously mentioned, it is further possible to make use of valve characteristics of the material in the parallel resistor rod, thus still further extending the range to which the fuse may be applied without excessive voltage surges.

Test Results

Important features of this fuse are the current-limiting fuse element and the voltage-limiting parallel resistor. The high arc voltage produced in the current-limiting fuse element and the effect of the parallel resistor in limiting that voltage are well illustrated in the oscillograms shown in figures 4 and 5. The tests represented by these oscillograms were made on a surge generator. Figure 4 shows the dynamic volt-ampere characteristics of the auxiliary fuse alone, while figure 5 shows the same characteristic of the auxiliary fuse and parallel resistor.

Numerous tests were made during the development of this fuse. Figures 6 and 7 show typical oscillograms of short-circuit interruptions on the fuse as finally perfected.

In figure 6 an interruption is shown on a 20,000-ampere 2,300-volt circuit. The fuse used in this test was similar to the illustration shown in figure 3, but of much smaller size, having an over-all length of only $4^5/_8$ inches. In this test it may be noted that the initial rush of current was limited at 175 amperes, while the surge voltage barely exceeded the peak value of the restored voltage.

Figure 7 shows an interruption on a 20,000-ampere 13.2-kv circuit. The fuse used in this test was as shown in figures

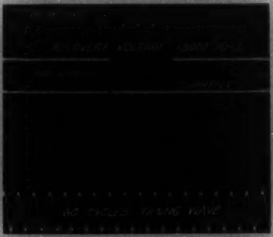

Figure 7. Operation of current-limiting fuse on a 13.2-kv system with 20,000-ampere available short-circuit capacity

An Electrical Governor

FRANK I. MORGAN
MEMBER AIEE

THE advantages obtained from the application of electrical methods of control to all classes of machinery, suggested to inventors the idea of regulating the speed of prime movers by electrical means. Frequent attempts have been made to accomplish this result. Many of these governors were very ingenious, but for one reason or another they never came into general use.

The electrical governor described in this paper is the result of several years effort to develop a practical method of electrically controlling and regulating the speed of hydraulic turbines.

Briefly, the method utilizes a form of frequency meter which measures variations in the frequency (corresponding to changes in speed) of an alternating current supplied by the generator driven by the turbine to be governed. This meter, through suitable control equipment, moves a pilot valve, which in turn controls the operating engine that opens or closes the wicket gates of the turbine.

An application of the scheme has been made to a 3,000-horsepower turbine operating under a head of 55 feet. The present installation is entirely experimental, the equipment being "home-made" and crude but the results obtained have been quite encouraging and indicate that the method has interesting possibilities.

A very steady speed is maintained at no load and synchronizing is done without difficulty with the governor in control of the unit. Operation under load is quite satisfactory, the governor responding promptly to small fractions of a cycle change in frequency (60 cycle). Changes in the loading of the machine are easily made, the governor responding instantly to such adjustments. Loads requiring gate openings of 80 to 90 per cent have been suddenly dropped by opening the generator circuit breaker. The governor closed the gates promptly and there was no tendency to "hunt" about the no-load position. Sudden accessions of load such as large "across the line" motors, are followed instantly by the opening of the turbine gates with no hunting whatever. The unit has been started from standstill many times by electrical remote control and when approximate normal speed was reached, placed under governor control by throwing a switch.

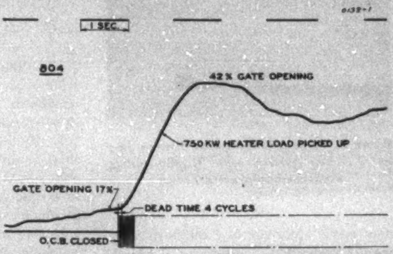

Figure 1. 750-kw load applied

Some of the advantages of electrical governing are:

(*a*). Small inertia of the control element.

(*b*). Increased sensitivity.

(*c*). Elimination of long rods, cables, bell cranks, etc., required for the compensation devices of fly-ball governors.

(*d*). Since, with electrical control, the force operating the pilot valve can be made large, and is independent of the amount of the speed change, friction in this valve has little or no effect.

(*e*). The possibility of mounting the control element at any convenient location, such as on the main switchboard.

(*f*). The valve controlling the admission of pressure fluid to the servomotor can be mounted immediately on this cylinder thus reducing the amount of piping and releasing valuable floor space ordinarily required for governors.

(*g*). Ease of starting and stopping the turbine by remote control. This permits *complete* control of the unit by the switchboard operator.

(*h*). Ease of applying frequency and load control methods.

(*i*). By means of simple test equipment, the sensitivity of the control element (frequency meter) of an electrical governor can be checked. A corresponding check of a fly-ball device is more difficult and complicated.

The writer is of the opinion that a description of the device and an account of the progress made up to the present, may prove of interest to engineers in general, and more particularly to those who are intimately concerned with governing problems.

Paper 40-132, recommended by the AIEE committee on power generation, and presented at the AIEE Pacific Coast convention, Los Angeles, Calif., August 27–30, 1940. Manuscript submitted April 2, 1938; made available for preprinting July 15, 1940.

Frank I. Morgan is maintenance engineer, Pennsylvania Water and Power Company, Baltimore, Md.

---

2 and 3 and has an over-all length of $12^1/_2$ inches. Here the initial rush of current reaches a maximum value of only 400 amperes, whereas the surge voltage is limited to 23 kv. Figure 8 shows a cathode-ray oscillogram of the voltage surge at the time of current limitation for the same test.

Summary

1. A new type of current-limiting fuse has been developed and tested.

2. The construction of the fuse is such that the voltage surge as well as the current surge during interruption is limited to definite and predetermined values.

3. Tests on high-capacity systems have not revealed the limitations of the fuse. Indications are that the fuse has an exceedingly high interrupting ability.

4. The design of the fuse is flexible. Time-current characteristics can be obtained as desired.

5. The fuses may be applied to the protection of potential transformers and other apparatus of small power consumption. They are especially applicable to use in enclosed switchgear.

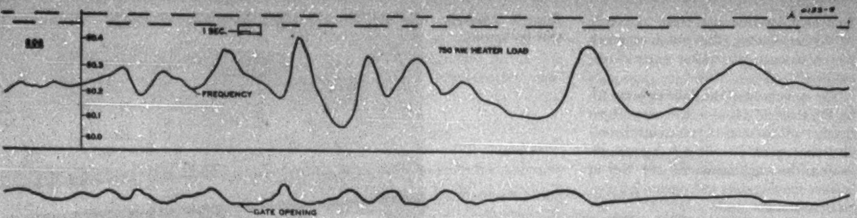

Figure 2. Frequency-gate movement

Preliminary Tests

The three tracings of oscillograms shown are a record of the performance of the governor during preliminary tests made in January and May 1937. These records are submitted, not as an indication of what can ultimately be accomplished, but simply to show the progress made up to the time of these tests.

The load on the unit during these tests was a purely resistance one amounting to 750 kw and it was possible to throw it on and off the unit at will.

Figure 1 (oscillogram number 804) shows the operation of the governor when a load of 750 kw was suddenly thrown on the unit. The governor started to open the gates in the remarkably short time of 4 cycles (60-cycle basis).

Figure 2 (oscillogram number 806) shows frequency and gate opening variations while the unit was carrying the load mentioned above.

Figure 3 (oscillogram number 808) gives the result of dropping load tests, showing the action of the governor when the load of 750 kw was dropped by opening the generator circuit breaker. The time required for the governor to start closing the gates varied from six to nine cycles.

Subsequent to the tests described in the foregoing, the apparatus has been applied to a double runner 13,500-horsepower turbine. This unit is equipped with a standard fly-ball governor of an old design. The control of its pilot valve was transferred from the flyballs to the electrical governor. The speed regulation, after the change, was very satisfactory and far superior to that obtained with the flyballs in control.

Operating Principle

An instrument sensitive to frequency variations and having two parallel electrical circuits, one branch containing resistance and the other reactance, is used as the control element. The change in impedance of the reactance with frequency is balanced by a corresponding change in resistance so that the currents flowing in the two branches of the circuit are maintained equal in value. The required changes in resistance are obtained by means of variable rheostats. Being a "null" method, the action of the control element is unaffected by changes in voltage within wide limits.

Referring to the schematic diagram, figure 4, *A* is a Kelvin balance employed as the frequency-responsive element, the moving coils of which are provided with a contact 27. This contact engages with either of the stationary contacts, 28 or 29. A resistance 10, is connected to one set of coils 3, and a reactance 11, to the other set of coils 2, of the Kelvin balance. Solenoids 24 and 25 actuate the walking beam 22, to which is connected the valve 18, admitting pressure fluid to either end of the "servomotor" cylinder 1. Rheostats 12 and 13 provide "compensation", the movable contact of rheostat 12 being connected to the servomotor piston rod by lever 30. The movable contact of rheostat 13 is connected to lever 30 by rod 33 and springs 31. A dashpot is provided to delay the movement of the contact of rheostat 13.

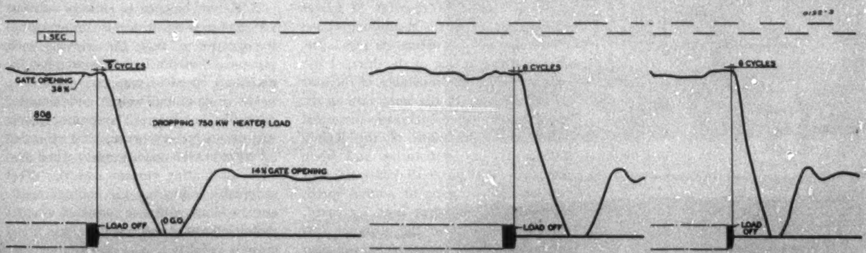
"Inherent speed drop" (also called "degree of irregularity," or the decrease in speed between no load and full load necessary for parallel operation) is adjusted by changing the location of the pivot point of rod 33 on the lever of rheostat 13.

The speed maintained by the governor is adjusted by means of rheostat 14.

Operation

Assuming normal frequency and steady load conditions, the currents flowing through the two sets of coils of the Kelvin balance are equal and the moving coils are in equilibrium, contact 27 being midway between contacts 28 and 29. Now, if the load on the unit increases, the speed will drop, lowering the frequency. Because of the lowered frequency, the reactance of 11 is decreased permitting more current to flow through coils 2 of the balance, upsetting the equilibrium of the moving coils. Contacts 27 and 29 close, energizing solenoid 24 which moves walking beam 22 and valve 18. Pressure

Figure 3. Dropping load tests



fluid then flows through pipes 20 and 21 to the servomotor, the piston of which moves to open the wicket gates of the turbine.

The movement of the walking beam 22, by the solenoid 24, also increases the resistance of rheostat 15 sufficiently to reduce the current in coils 2, to normal, restoring the equilibrium of the Kelvin balance moving coils and separating contacts 27 and 29.

The opening of the wicket gates by the servomotor increases the resistance of rheostat 12 by moving lever 30. This additional increase of resistance in series with coils 2 unbalances the moving coils in the opposite direction, closing contacts 27 and 28 to energize solenoid 25, which moves walking beam 22. This results in return of valve 18 toward its neutral position, and at the same time, decreases the resistance of rheostat 15. It should be noted that the movement of valve 18 back to its neutral position is simultaneous with the opening of the gates by the servomotor and the increase in resistance of rheostat 12.

When the resistance of rheostat 12 has been increased by an amount equivalent to the decrease in impedance of reactance 11 and the increase in resistance of rheostat 15 by the initial movement of the walking beam, the equilibrium of the Kelvin balance is again restored and valve 18 has been brought back to its neutral position, stopping movement of the gates.

The wicket gates have now been opened to increase the amount of water to the turbine, but because of the inertia of the water, its flow does not immediately increase. During the time the gates are being opened to the new load position and until the flow of the water increases sufficiently, the additional load demand is met by energy stored in the revolving parts of the turbine and generator which is released by a decrease in speed. As the flow of water increases through the greater gate opening, the speed of the unit returns toward normal. Unless provision is made to prevent it, this increase in speed (and frequency) toward normal would upset the equilibrium of the Kelvin balance—which has been balanced for the lowered speed of the unit by the change in resistance of rheostat 12—and cause a closing movement of the gates. This is avoided through the action of springs 31, rheostat 13, and the dashpot. (Second compensation.)

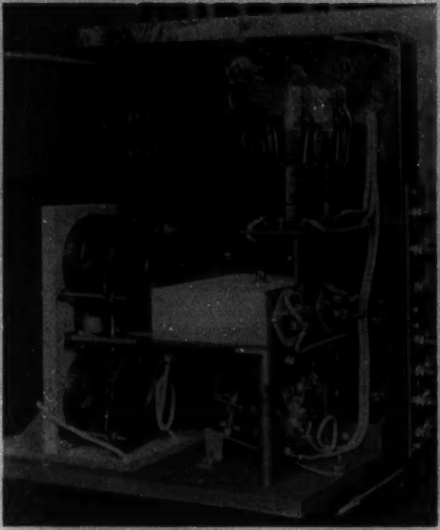


Figure 5. Magnetic vane instrument

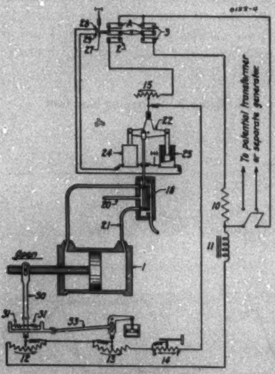

Figure 4. Schematic diagram

The tension of the spring 31 has been increased by the movement of lever 30, and the contact of rheostat 13 moves slowly, because of the restraining action of the dashpot, to reduce its resistance. Provided the setting of the dashpot bypass is correct, the resistance of rheostat 13 will decrease at the same rate as the speed (and frequency) increases to normal value, the equilibrium of the Kelvin balance will not be disturbed and, when movement of rheostat 13 ceases, the unit will be again running at normal speed, although the load has been increased. Circuit conditions of the governor (assuming isochronous adjustment) will then be exactly as they were before the change of load occurred.

It is apparent that increasing the resistance of rheostat 14, has the same effect as an increase in impedance, of reactor 11, resulting from an increase in speed (and frequency) of the turbine. Such an increase of resistance will cause the governor to close the turbine gates by a definite amount and lower the turbine speed.

Conversely, a decrease in resistance of rheostat 14 will cause the governor to open the turbine gates and increase the speed of the turbine.

The action of the governor on a decrease in load is, practically, the reverse of that described in the foregoing.

Control Instrument

A Kelvin balance is entirely satisfactory as far as sensitivity is concerned but it was found that the moving coils possessed too much inertia to give the necessary speed of response, even when made of minimum weight and mounted in jeweled bearings. The contact system was unsatisfactory because the vibration inherent in such an instrument when used with alternating current had the effect of greatly increasing the contact resistance. Many different forms of contact mounting were tried but none was found entirely reliable.

A magnetic vane instrument, shown in figure 5, was constructed and substituted for the Kelvin balance. The moving element of this instrument consists of a small aluminum shaft fitted with steel pivots, on which two light annealed steel vanes are mounted. This shaft is supported in jeweled bearings. Each vane is surrounded by a coil, one of which is connected in series with resistance 10, the other being connected in series with reactance 11. The vanes are placed on the shaft at an angle of approximately 80 degrees with respect to one another so that, with current flowing through the two coils, they tend to move in opposite directions and the shaft assumes a position depending on the relative strengths of the currents in the two coils. The moving element is dampened by a small oil dashpot. A small mirror is mounted on the shaft midway between the ends.

Figure 6. Compensation rheostats

Light from a 21 candle-power automobile head lamp is reflected from the mirror to two photoelectric cells which are connected to the grids of two vacuum tubes. The two coils of a differential relay of the D'Arsonval type are connected in the plate circuits of the tubes. The contacts of this relay control the solenoids 24 and 25 which operate valve 18.

The use of a lamp and vacuum tubes naturally raises the question of reliability since that feature is of paramount importance in a governor.

Records of lamp life, in continuous telemeter service, have shown that the life of such lamps (6–8 volts) when operated at 4 volts, varied from 12,000 to 19,000 hours.

An effective means of insuring reliability is the use of a double filament lamp (number 2331) and two sets of vacuum tubes. A simple one-contact relay operates to connect the second set of tubes and the second lamp filament in the event any one filament fails in the first set. If desired an alarm contact could be added to the relay.

Power Requirements

The magnetic vane instrument requires about 30 volt-amperes for its operation including the 21 candle-power lamp and the filaments of the vacuum tubes. This indicates that the load on a potential transformer for this type of governor would be quite negligible and makes feasible the use of a small magneto for this purpose if it were considered undesirable, from the standpoint of reliability, to use potential transformers.

Governor Action on Loss of Load

When a heavy load is suddenly dropped from a hydraulic turbine, the speed immediately increases and the governor promptly closes the gates. Because that part of the compensation device (second compensation) which contains the time delay feature acts slowly, the speed reaches its highest value and decreases toward normal before the time delay element has returned to the point where it can function properly for the gate opening required to maintain normal no-load speed. As a result, when the speed decreases sufficiently to cause the flyballs to start opening the gates, the second compensation cannot operate properly and the gates are opened far beyond the point necessary to maintain normal speed at no load. The turbine overspeeds, causing the flyballs to again close the gates completely. During each interval of gate closure, the second compensation approaches the position where it can function properly. Until it reaches this point, these gate opening and closing cycles repeat at intervals with gradually decreasing amplitude. The effect, for the time being, is much the same as that which would be obtained if the second compensation feature were omitted.

This objectionable operation has been remedied in one well-known make of governor by means of a cam which increases the action of the spring which opposes the centrifugal force of the flyballs. This cam begins to be effective when the gates, on closing, reach the point which admits sufficient water to operate the turbine at about normal speed with no load. The cam increases the "regulation" of the governor at no load, i.e., it adjusts the flyballs so that the speed maintained at no load is considerably higher than that at full load. In other words, the cam provides additional compensation for a limited range of gate movement. In this way, as the turbine

Figure 7. Pilot-valve solenoids

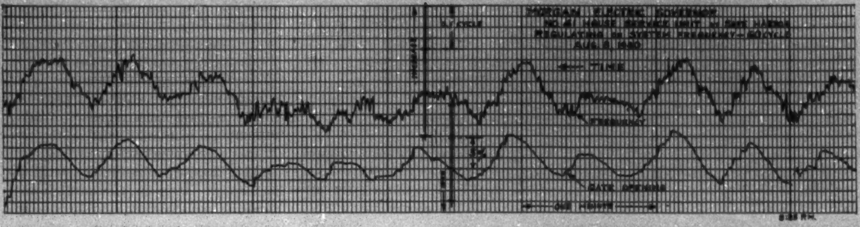

Figure 8. Record of test made August 8, 1940

slows down, the flyballs start to open the gates sooner than they would had no adjustment been made, the downward trend of the speed is arrested earlier and the second compensation functions properly. In addition, the opening movement of the gate is stopped at a point at which the readjusted speed will be maintained.

In at least two other makes of governors, this surging of gate movement and speed after dropping heavy loads is avoided by the provision of a bypass for the dashpot, which is opened automatically when quick gate movements beyond a certain amount occur.

In the governor described above, a bar is used to connect the movable levers of the compensation rheostats 12 and 13. This bar is slotted at the end connected to the lever of rheostat 13, as can be seen in figure 6. The purpose of this bar is the return of the lever of rheostat 13, on large, quick gate movements to a point where the second compensation can function properly. The slot allows the second compensation to operate normally on small gate movements or large gate movements which do not take place rapidly. This method of overcoming the faulty operation mentioned above has the advantage that no change is made in the regulation of the governor.

Load Limit and Safety Devices

Limitation of the load carried by the unit can be accomplished by arranging a stop, operated by an electromagnet, to prevent movement of walking beam 22 and valve 18 to cause further opening of the gates. The electromagnet would be energized through suitably arranged contacts to be closed by lever 30, these contacts to be adjustable so that the gate opening could be limited to any degree desired. This arrangement would not interfere with the closing of the gates at any time.

Emergency shutdown of the unit could be accomplished by the use of a relay, which when de-energized, would release a spring to move the pilot valve, independently of solenoids 24 and 25, in the direction to close the turbine gates. The relay releasing the spring could be operated by over-speed, over or undervoltage, decrease in governor fluid pressure below a definite value, etc.

Conclusion

No claim is made that the method of governing described in the foregoing is the ultimate solution of the problem of regulating the speed of hydraulic turbines. It is readily apparent that the results obtained, so far, with this experimental set-up, are more or less academic in value, and that the real worth of the method can only be determined by considerable operating experience which will bring out the weak points and emphasize those which are of advantage.

One possibility which may be deserving of consideration is the ease with which this equipment can be applied to obsolete or antiquated pressure operated governors and thereby secure the sensitivity and satisfactory operation of a modern governor without the expense of replacing the entire installation.

A High-Power Oilless Circuit Interrupter Using Water

W. M. LEEDS
MEMBER AIEE

THE oil circuit breaker has been for many years the standard type of circuit interrupter for heavy-duty power-house service. Since the introduction of modern arc-rupturing devices into these circuit breakers, the occurrence of serious trouble attributable directly to oil switchgear failure has been rare. However, the appearance on the market of various types of oilless circuit breakers of considerable interrupting capacity has encouraged the idea that the complete elimination of oil in power house switchgear may be both desirable and practicable. Further experimental investigation and development activity on the part of switchgear manufacturers seems to indicate that currents of 60,000 amperes or more at 13,200 volts can be interrupted satisfactorily in circuit breakers using either air or water as the arc-quenching medium. This paper describes the construction and operating characteristics of a high-power water circuit breaker.

Water Circuit Breakers

Interrupters using water as the extinguishing medium have a history of some 15 years, and are now used fairly extensively in moderate interrupting capacities, particularly in Germany.[1] In the form designated as "expansion breaker", the arc is drawn in a confined chamber where the generation of steam and gas quickly builds up a high pressure. The chamber is usually constructed of one or more sections resiliently mounted so that passages to a condensing chamber are opened up by the pressure, as indicated in figure 1. It is claimed that the deionization of the arc space is greatly accelerated by the cooling effect accompanying the sudden expansion of the steam. In any case, it is certain that the arc is subjected to a turbulent blast of steam and gas as these arc products make their escape laterally or longitudinally from the recesses in the interrupting chamber. The combined effect of cooling and turbulence causes dielectric strength to be built up with sufficient rapidity that the arc will not restrike.

Since even distilled water is a relatively poor dielectric the moving contact must be lifted clear of the water, and in many designs moved completely out of the chamber so as to interpose a series air break. The condensation of a large proportion of the vapors considerably reduces the external demonstration as compared with an oil breaker, the operation being somewhat quieter than an air switch. Factors which prevent this device from fulfilling the requirements of an ideal breaker include contamination and loss of water, and the possibility of corrosion of metal parts and deterioration of the insulation exposed to water or steam. Nevertheless, these problems are not at all insuperable, and high-capacity water breakers of the type described have been made experimentally for ratings up to 1,500,000 kva at 15 kv.

Water-Breaker Construction

Investigations on the breakdown of water under electric stress, by J. Slepian, C. L. Denault, and A. P. Strom,[2] indicate the desirability of not only removing voltage completely from the interrupting chamber immediately after opening the circuit, but also closing the circuit by an air switch rather than in the water. The experimental water-breaker pole unit shown in figure 2 is arranged with a series disconnect switch and also a main paralleling switch for continuous-current-carrying ratings of 1,200 amperes and above. The pole-unit mechanism is arranged to give the following sequence of operation:

Closing

1. Arcing contacts close in water.
2. Series disconnect switch completes the circuit in air.
3. Main switch closes, paralleling the arcing contacts and disconnect switch.

Opening

1. Main switch opens, diverting the current through the arcing contacts.
2. Arcing contacts open, extinguishing the arc in the water chamber.
3. Series disconnect switch opens, removing potential from the interrupter.

The different positions of the breaker contacts are illustrated in figure 3.

Although condensation reduces the amount of gas vented to the outside of the breaker, heavy local pressure impulses created in the neighborhood of the arc, when interrupting very high currents require exceptionally strong construction of the main body of the interrupter. Figure 4 is a cross section of the interrupting chamber. Overlapping inside and outside bronze cylinders *A* hold a heavy insulating tube *B* in compression and shear to develop maximum strength. Special attention has been given to the problem of shock absorption by providing a large air volume above the water level and also by utilizing the compressibility of air pockets sealed in rubber *C* located in the removable bottom bronze bell cover *D*.

The stationary arcing contact assembly consists of a cluster of fingers *E* while the arcing contact itself is made of a strong rustproof alloy rod *F* with a tip of arc-resisting material. This contact moves in and out of a chamber formed by three large blocks *G* of special insulating material with a centrally located water trapping pocket in each. A hollow spacer *H* above these blocks engages a rubber ring *I*. Pressure under the lowest block raises the whole arcing chamber assembly, compressing this rubber ring and at the same time opening the vent *J*.

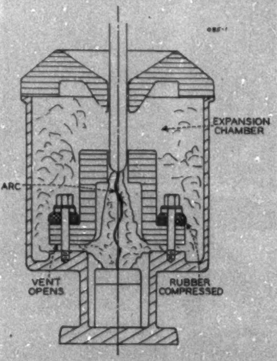

Figure 1. Siemens expansion breaker for low voltage

Paper 40-85, recommended by the AIEE committee on protective devices, and presented at the AIEE summer convention, Swampscott, Mass., June 24–28, 1940. Manuscript submitted November 13, 1939; made available for preprinting April 23, 1940.

W. M. LEEDS is electrical engineer in the switchgear engineering department, Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.

Among those of the author's associates who have aided in the development of this water breaker he wishes to acknowledge particularly the contributions of A. J. A. Peterson and A. H. Bakken in creating a workable mechanical design and the untiring efforts of B. P. Baker in following through the construction and testing of the experimental pole unit.

Figure 2. 15-kv water breaker experimental pole unit set up for interrupting tests

While research work by Kesselring and others in Germany might seem to have shown that arcs can be extinguished by the cooling action accompanying sudden expansion of saturated vapors surrounding an arc, it is not believed that this high-power water breaker operates in quite the same manner. For instance, no attempt is made to synchronize the opening of the vent and resultant vapor expansion with the instant of current zero. When interrupting a high-current arc, the vent *J* begins to open during the first half cycle of arcing. As the contact tip draws the arc *K* into each successive water pocket, more steam and dissociated gases are formed which turbulently mix into the arc stream on their way to the vent *J*. It should be noted further that the upward displacement of the interrupting elements *G* and *H* as the rubber ring *I* is compressed reduces the volume of the space between the upper block and the contact guide. This results in a quantity of water being forced in a longitudinal flow down along the contact and into the arc stream, tending to sweep the arc products downward and away from the contact tip. The deionization produced by the turbulent flow of the relatively cool water vapor and steam through the arc space is so effective that at the first or second current zero after the arc is drawn into the bottom of the arcing chamber, the dielectric strength builds up with sufficient rapidity that reignition cannot take place and the arc is extinguished.

J—Arcing chamber vent

When interrupting lower currents the valve-type vent *J* opens only a very small amount, maintaining fairly high pressure in the arcing chamber. This keeps the gas bubble small, so that effective deionization is still obtained and the arcing time is only slightly longer than at high currents. By using only the one vent at the bottom instead of at several points along the arc stream all of the gas is

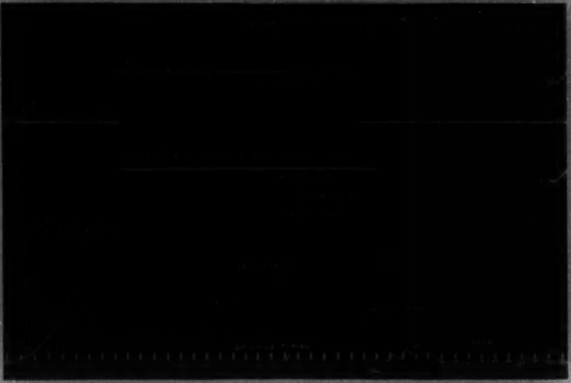

Figure 6. Oscillogram of low-current interruption at 13,200 volts

forced through the restricted arc passage and the deionizing action thus intensified.

The steam and gas from the vents are directed through a condensing labyrinth, shown in figure 5, and the permanent gases such as hydrogen and carbon monoxide that remain after the water vapor is removed pass out of a small port to the atmosphere. The amount of vented gas is estimated to be only about ten per cent of the total quantity generated by the arc, thus making possible almost complete enclosure of the interrupter. Water and steam that may be forced out around the upper contact guide is not thrown out of the breaker but only up into the mechanism chamber. Leakage from the chamber is avoided by providing a close-fitting bushing for the rotating shaft which operates the arcing and disconnect contacts.

Test Results

In table I are recorded a few of the results from the many series of interrupting tests on this water-breaker pole unit. A current range of 50 to 61,000 amperes at 13,200 volts is covered in these tests, the arcing time averaging close to 1½ cycles for all currents. Oscillograms of representative opening and close-open interruptions are shown in figures 6, 7, 8, and 9. These show that for only the last one or two half-cycles of this time is there appreciable arc voltage, indicating effective action as soon as flow through the arcing chamber is established. The closing of high currents on the air-disconnect-switch contacts is accomplished with very little arcing due to the high-speed snap action. On the opening stroke, this switch shows a small spark when clearing the very low residual current conducted through the water in the arcing chamber immediately following the interruption of the main arc. The burning at the main contact and fingers is found to be very moderate considering the length of the current path through the arcing contact and disconnect switch to which the short-circuit current must be transferred by the opening of the main paralleling switch.

Distilled water is used in the breaker, samples from the interrupter usually measuring about 100,000 ohm-centimeters just after filling. The tests indicate that 100 or more low- and medium-current interruptions can be made before the resistivity will go to a value which indicates the need for water replacement. From four to six short circuits in the range from 40,000 to 60,000 amperes can be interrupted without changing the water in the breaker. The interrupting effectiveness of this water breaker design is clearly demonstrated by the fact that although the full operating line voltage was applied across a single-pole unit, the arc was quickly extinguished after separating the arcing contacts only a few inches in the single interrupting chamber.

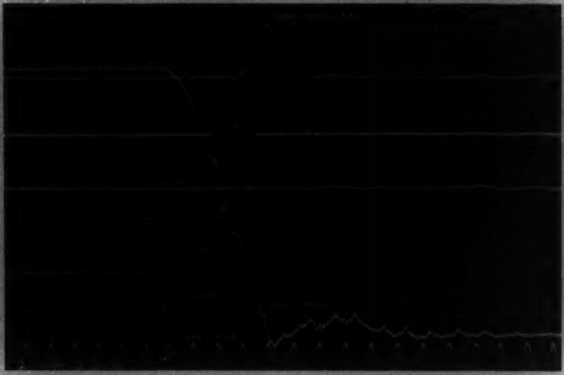
Figure 9 (below). Oscillogram of opening test interrupting 61,000 amperes at 13,200 volts



Advantageous Design Features

Features of particular interest in the design of the water breaker just described are as follows:

(*a*). The bottom bell *D*, figure 4, is readily removable for access to the stationary contact structure without disturbing the mounting of the pole unit.

(*b*). Because of the top enclosure of the pole unit, very little water or gas can escape into the surrounding air when the breaker is opening short circuits. The outlet for gas is designed to strain moisture from it before it reaches the atmosphere.

(*c*). No porcelain is used in the construction of this breaker.

(*d*). The main current-carrying loop being at the rear of the pole unit is of minimum length, and the severe mechanical strains caused by short-circuit currents which occur in many designs are not present in this one.

Conclusions

Tests on a high-power water breaker have shown that water can be used as an arc-extinguishing medium with results comparable to an oil circuit breaker. With proper precautions in the design which take into account the relatively low dielectric strength of water and the possibilities of corrosion, the water breaker becomes very interesting. As further experience is obtained it may find a place in the field of oilless switchgear for central-station service in America as it has in Europe.

A Power-System Governor Sensitive to Frequency and Load

THOMAS E. CURTIS
ASSOCIATE AIEE

Synopsis: This paper describes a new electrical control system with which a standard power-system governor may be made sensitive to system load as well as frequency. A proposed scheme of application is presented which is believed to permit electrical control of a standard governor instead of mechanical control, without any sacrifice of reliability.

THE frequency of a power system is governed by controlling the power input to the prime movers of the system. Consider, for example, a typical power system in which one hydraulically-driven synchronous generator is governing the system frequency. Since the remaining generating units are operating at constant loads, the power output of the governing unit must be regulated so that the unit will assume any variations of load on the system. Simultaneously, this unit is controlled to hold the system frequency at a constant value.

Figure 1 is the schematic representation of a typical governing system of a hydro-electric generating unit. The power output of this unit is regulated by varying the opening of the needle valve to control the flow of water through the turbine This valve is operated by oil pressure through a control valve and piston, as shown in figure 2. The speed-sensitive element in this governing system is a centrifugal governor, driven from the turbine shaft, which operates the control valve by pivoting the beam about point P.

To meet changing system load, the load level of the governor is varied by the electrically-operated load control. The load control is operated through a contact-making frequency meter, connected to the system, which periodically resets the motor to change the relationship between the elevation of point P and the opening of the needle valve. The governor operation is thereby made isochronous.

It is now pointed out that the governing system just described is actuated by turbine speed and system frequency. A definite time lag must then exist in its operation to compensate for system load changes, since the rate of change of frequency which results from a differential between power generated and power demanded must exist for a definite period of time before frequency and turbine speed change sufficiently to actuate the governor. It is the purpose of this paper to describe a new governing system which is sensitive to both frequency and load.

Operating Principle

Figure 3 is a schematic representation of the proposed governing system. The turbine governor is actuated by an electronic frequency controller, through the medium of a balanced solenoid. This frequency controller provides two distinct components of control to make the governor sensitive to both frequency and load. The first component is derived from the pair of d-c currents I_A and I_B as functions of α, the rate of change of frequency in cycles per second per second. The second component is derived from the pair of d-c currents I_C and I_D as functions of F, the frequency in cycles per second. The controlling currents I_A, I_B, I_C, and I_D are obtained through the use of vacuum-tube circuits in the frequency controller. The characteristic operating curves are shown in figure 3. Current values are indicated in milliamperes. The solenoid plunger is then displaced from its central position in proportion to the current unbalance between I_A+I_C and I_B+I_D. An unbalance of I_A and I_B then actuates

the governor instantaneously whenever equilibrium is disturbed between power generated and power demanded. An unbalance of I_C and I_D actuates the governor whenever frequency deviates from its normal value.

The balanced solenoid operates the governor control valve through the conventional mechanical linkage, similar to that shown in figure 2. However, the standard centrifugal governor is retained on a separate beam. The controller beam and the governor beam have a common pivot at one end. At the other end, there is an interlocking pivot arrangement which couples to either one beam or the other. The solenoid M is energized to transfer *from* the governor beam *to* the controller beam. Signal lights S indicate which beam is in use. Four limit contacts are attached to the assembly of the interlocked pivots. One of these will make contact with whichever beam is uncoupled should any condition arise which disturbs their normally parallel operation. The limit contacts will then operate time-delay relays R_3 and R_4 to transfer control to the governor beam, or to prevent closing to the controller beam when conditions are not correct. The relays have a time delay in order to prevent their operation by the load-sensitive component of control during the course of normal operation.

Isochronous control is provided by the periodic polarized relay R_2, which operates the load-control motor through relay R_1. R_3 has auxiliary contacts which block the operation of R_1 to raise the load level when R_3 has tripped. Similarly, the tripping of R_4 blocks the operation of R_1 to lower the load level. These blocking circuits protect the governor from faulty operation of the load control. As indicated in figure 3, automatic time control may be coupled in at relay R_2.

Due to the use of balanced circuits throughout the frequency controller, it is possible to place a balance relay R_6 in the common-current return to terminal E. Any fault conditions within the controller will change the current in R_6, thereby tripping R_6 instantaneously to transfer control to the governor beam. By shorting out R_5, the tripping of R_6 also prevents possible erroneous operation of the load control. Control is automatically transferred to the controller beam when the current through R_6 returns to normal, provided that the transfer circuit has not been opened by either R_3 or R_4.

As outlined above, the control system is protected against faults within the controller by balance relay R_6. If, for any reason, R_6 should fail to operate, either R_3 or R_4 will transfer control to the governor beam. Relays R_3 and R_4 provide a continuous check of the calibration of the frequency controller against the centrifugal governor.

For the sake of simplicity, the load-limiting control is not indicated in figure 3. See figure 2.

The operation of the control system for a sudden increase of load is indicated in figure 4. The curve I_D-I_C represents frequency deviation, and curve I_B-I_A represents rate of change of frequency. The solenoid operation is represented by the sum of these two curves, $-I_A+I_B-I_C+I_D$. The shaded area A for time T represents the net improvement in control that this proposed control system provides over and above that of existing governing systems. The operation of the load-control motor is indicated at the bottom of the figure.

Solenoid Characteristics

In figure 5 are shown the operating characteristics of the balanced solenoid. The ordinates D represent the displacement of the plunger from its central position. The force-versus-displacement curves for each coil change with the frequency applied to the controller. Thus, for an applied frequency of 60.5 cycles per second, the force curves of the two coils intersect at P_3, whose ordinate is the displacement assumed by the plunger. When the frequency applied to the controller is 60 cycles, the force curves intersect at P_4, where the plunger displacement D is equal to zero.

If a differential force dF is applied to the plunger, it can move through a displacement D_2, as indicated. This differential force may represent either the threshold force of the valve linkage or a

Figure 3. Proposed governing system

force tending to produce oscillation. In figure 6, which indicates the equilibrant forces of the centrifugal governor, it can be seen that the same differential force *dF* produces a relatively greater displacement D_1. Therefore, in comparing a centrifugal governor with a balanced solenoid operating in the same force range, the threshold limit of operation and the magnitude of possible oscillation of the solenoid is about one-half that of the former.

Curve *A* in figure 6 represents the restraining force of the centrifugal governor. The operating displacement is determined by its point of intersection with the lifting-force curve corresponding to the system frequency and turbine speed.

Controller Circuit

Figure 7 is the schematic circuit diagram of the frequency controller. System frequency is supplied to the controller through transformer T_1. A capacitance C_1 is connected in the circuit of one secondary winding, and an inductance L_1 is connected in the other. As frequency increases, the a-c current through R_1 decreases, while that through R_2 increases. The magnitudes of the a-c voltages appearing across R_1 and R_2 are converted into correspondingly proportional d-c currents in R_9 and R_{10}. This conversion is accomplished by vacuum tubes V_1, V_2, V_3, V_4, V_5, V_6, V_7, and V_8. Phase-shifting circuits C_2–R_3–C_3 and L_2–R_4–L_3 convert the single-phase voltage across R_1 to four-phase star voltages at the grids of tubes V_1, V_2, V_3, and V_4. Since the tubes are biased to cut-off, their action is that of rectification. The phase displacement of the plate-current pulses is such as to provide a nearly uniform current in R_9. Circuit C_6–L_6–C_7 filters out the remaining current ripple. The function of V_5, V_6, V_7, and V_8 is similar to that described above for V_1, V_2, V_3, and V_4, except that frequency response is inverse. Polyphase rectification is employed since it is essential that the d-c currents in R_9 and R_{10} should have a minimum ripple. Also, in order to minimize reactive transients, it is desirable to use polyphase rectification in order that circuits C_6–L_6–C_7 and C_8–L_7–C_9 may have a low reactance.

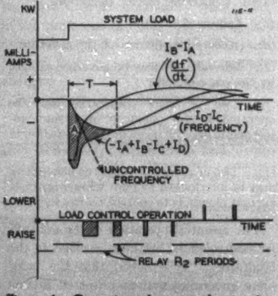

Figure 4. Operation of proposed governing system for abrupt load increase

The d-c voltage across R_9 and R_{10} is a function of the frequency applied to T_1. This voltage is center-tapped by R_{11} and R_{12}, and applied to the grids of V_9 and V_{10}. The plate currents flow through two windings of transformer T_2 and R_{15} and R_{16}. The voltage across R_{15} and R_{16} is applied to V_{15} and V_{16} to provide currents I_C and I_D, as shown in figure 3.

A voltage appears across the secondary winding of T_2 when the plate currents of V_9 and V_{10} are changing with respect to time. This voltage is therefore a function of the rate of change of system frequency with respect to time. It is amplified by V_{11} and V_{12}, and converted by V_{13} and V_{14} into currents I_A and I_B, also as in figure 3.

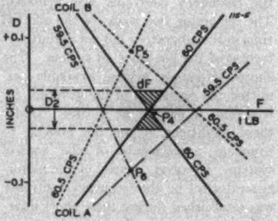

Figure 5. Equilibrant forces of balanced solenoid

An alternative scheme for obtaining the load-sensitive component of control is the use of two capacitors and two resistors instead of the transformer T_2. This replacement of transformer T_2 is indicated in figure 8. A d-c current flows through R_{29} and R_{30} in response to a rate of change of potential across R_{15} and R_{16}. The voltage drop across R_{29} is then applied to the grid of V_{12}, while that across R_{30} is applied to V_{11}.

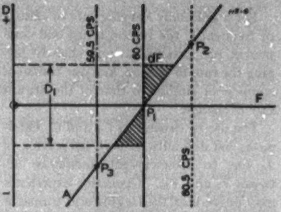

Figure 6. Equilibrant forces of centrifugal governor

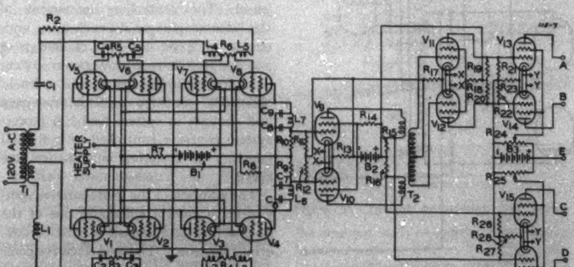
The response of the load-sensitive component of control is not strictly accurate when capacitors are used instead of the transformer. Thus, for a suddenly-applied frequency rate of change, the voltage response at the grid of V_{11} is:

$e = k_1k_2R_{30}C + k_3R_{30}e^{-t/rC}$
k_1 = time constant of applied rate of change of frequency
k_2 = voltage—frequency constant across R_{15} and R_{16}
k_3 = constant depending upon capacitor voltage conditions
C = series capacitance of C_{10} and C_{11}
$r = R_{29} + R_{30}$
t = time in seconds

It will be observed that the first term is directly proportional to the frequency rate of change. The second term is a capacitive transient during the initial period of the change while voltages are seeking their proper relationships. During tests, this transient was observed to be of the order of one-half second.

Figure 7. Schematic of frequency controller



For a gradually varying rate of change of frequency, the response has one component proportional to and slightly lagging the rate of change, and one transient component similar to that of the abrupt rate of change.

The use of capacitors C_{10} and C_{11} eliminates the difficulty of core saturation of T_3 due to plate-current unbalance between V_9 and V_{10}. Operating experience may prove that the lagging and transient components present with the use of capacitors have no deleterious effect upon the quality of the frequency control.

The characteristics of the controller are readily variable. While maintaining the same normal current, the slopes of the I_A and I_B curves may be varied by adjusting R_{19} and R_{20}. Similarly, the slopes of the I_C and I_D curves may be varied with R_{15} and R_{16}. The current level of I_A and I_B is controlled by R_{24}. That of I_C and I_D is controlled by R_{25}. The normal operating points of the controller are independent of voltage variations at T_1. Supply-voltage variations affect only the slopes of the characteristic curves. The variation in slope is approximately proportional to the voltage variation. However, the effect of such variations is negligible.

Tests

The solenoid-operated control valve used in testing the frequency controller is shown in figure 9. The over-all length of this valve is seven inches. The operating piston, or servomotor, was operated by oil flowing through the two valve ports near the center of the valve. The component parts of the valve are shown in figure 10. This photograph shows the rear view of the brass valve cylinder. Oil under pressure was supplied to the center connection. Oil discharged from the operating piston passed through the outer two connections. The soft-steel valve plunger moves longitudinally through the two solenoid coils. The two center flanges match the valve ports shown in figure 9. Small diagonal holes were drilled through the flanges in order to revolve the plunger by the reaction of oil passing through. This rotation of the plunger maintained its freedom of movement. The two coils were connected to the frequency controller. Through the medium of the solenoid valve, the controller then controlled a piston-operated rheostat in the field circuit of a d-c shunt motor. This motor drove a 15-kva synchronous generator, from which the frequency controller was operated. The remaining two weeks of the allotted time in the laboratory did not permit perfection of the governor oil system. The simple oil-supply system available permitted the operation of the governor for less than a minute at a time. Under these conditions, it was not possible to complete adjustments of the control system. However, control of the motor-generator set by the frequency controller was established during these short intervals.

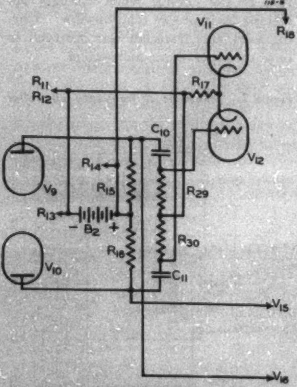


Figure 8. Alternative load-sensitive circuit for substitution in figure 7

Conclusions

A new electronic system of frequency control has been developed in the laboratory. It is believed that this control system can be adapted to standard hydraulic governors now in use.

The electronic frequency controller described in this paper provides movement of a solenoid plunger comparable to the controlling movement of a fly-ball governor. The controlling movement of a fly-ball governor depends upon change of speed. The controlling movement of the solenoid plunger depends upon both change of speed and rate of change of speed. It follows that a power-system governor controlled by such a solenoid should be sensitive to both frequency and changes in system load. A power-system governor controlled by a fly-ball governor is sensitive only to turbine speed.

The addition of the load-sensitive component of control eliminates one of the several time lags present in existing governing systems. The load-sensitive component of the solenoid motion actuates the governor to oppose hunting swings.

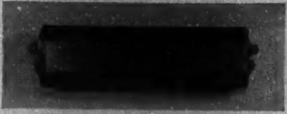

Figure 9. Solenoid-operated control valve used in tests

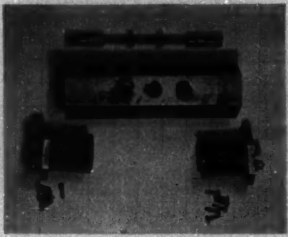

Figure 10. Component parts of control valve

It is believed that the solenoid described in this paper can be substituted, with no sacrifice of reliability, for the standard fly-ball governor head, provided that the latter is retained in a stand-by capacity.

The scheme of controlling machines in accordance with both speed and rate of change of speed is not new, as inertia governors have been used for many years in some applications other than electric power systems. It is believed, however, that the electronic control system herein proposed has the following advantages over the mechanical inertia governor:

(*a*). Response to rate of change of frequency separately adjustable during operation.

(*b*). Response to frequency deviation separately adjustable during operation.

(*c*). Increased sensitivity.

(*d*). Reduced oscillation of the governor.

(*e*). Several units may be governed at once by the one controller.

(*f*). Two or more controllers may be operated on the system at once, since adjustments may be made during operation to control load division.

(*g*). Two or more controllers on one system may be interlocked by pilot wires or carrier-current channels to control tie-line loads.

The essential operation of the controller and solenoid has been verified in the laboratory. It is hoped that the complete governing system proposed in this paper may be submitted to the test of operating experience in the near future.

Automatic Printing Ammeter

T. G. LE CLAIR
FELLOW AIEE

Synopsis: A new instrument has been developed which will automatically read and record in numerals, at predetermined time intervals, the ampere loading on 50 different electric circuits. This instrument also adds the readings on groups of circuits and prints these totals in columns beside the ampere load readings. The paper outlines briefly the reasons for developing such a device. The paper also describes, with the aid of schematic diagrams, the process by which the instrument obtains and prints all the measurements and totals on a single "log sheet."

Need for Compact Ammeter Records

THE rating of most electrical equipment is on an ampere basis. To determine when additional capacity in lines, transformers, or generators, is required on a power system, it is necessary to have an accurate record of past ammeter loads. For maximum usefulness, these ammeter records should be as compact and legible as possible for ready determination of the shape of the load curves and rate of growth.

In large power stations it is common practice for an operator to note and record on a "log sheet" the ammeter readings on all outgoing transmission lines at frequent intervals. When several of these outgoing lines supply the same load it is necessary to totalize the loads on all lines in a given group in order to estimate the load growth on the combined group. Figure 1 illustrates a typical group of substations fed by several lines from the same generating station. When 50 to 100 or more lines emanate from the same station the instrument readings must be recorded with a minimum of effort and in the most usable form. Recording instruments would be suitable for this purpose if their record could be compact enough.

Substations such as substation *A* in figure 1 may frequently be of an unattended type. In such a substation it is desirable to have ammeter records in convenient and compact form of the loading on transformers and distribution feeders. It is also desirable to obtain these records automatically, to avoid the expense of an attendant.

Available Types of Instruments

At present a number of types of instruments are available which can be used for obtaining compact records automatically. The most common type, of course, is the ordinary graphic instrument with one instrument installed on each circuit. These instruments are available with charts for various periods from one day up. There is also available a graphic instrument for ten circuits which, instead of drawing a load curve, puts on the graph paper a series of characters so that the line connecting the same characters is the equivalent of a graphic record. For totalizing the readings of several circuits, equipment is available by which either amperes or watts, a-c, can be converted to a d-c voltage, and the d-c voltages from several of these converters connected in series on a d-c instrument for a totalized reading.

In Chicago unattended substations the practice has been to use graphic instruments for ammeter records. In generating stations compact recordings of line readings are obtained by having an operator read a series of indicating instruments and record these readings on a log sheet in rows and columns. The usual arrangement is that each column represents the readings on a given circuit and each row is the series of readings taken at a given time. An increasing need was felt to relieve the operator of this burden in large stations, or to obtain these readings in substations where an operator is not on hand for 24 hours a day. This need resulted in the development of a measuring combination with the following basic principle:

Fundamental Principle of New Instrument

A single accurate measuring device is constructed which is automatically connected in turn to each of the circuits to be measured. The single measuring device is used in combination with a printer which records on a log sheet figures which are a measure of the magnitude of the current. The column position of a given reading on the log sheet signifies the circuit on which the reading was taken. The row position of the reading on the log sheet signifies the time when the reading was taken. The measuring device itself utilizes a balancing relay in which the current to be measured is balanced against the current from a standardizing source which is co-ordinated electrically to the printing device.

The totalizing of the readings is accomplished by means of additional mechanism which prints the total figures beside the readings which have been totalized. The new instrument eliminates the human error, both in the accuracy of the readings and in the timing of the periodic readings.

Laboratory Development

A simple experimental instrument was built first to show that the measuring principle would work. Later a full size model was made to record all the ammeter readings in one supervisory control substation. The complete model is shown in the photograph, figure 2. This model was constructed in the laboratory from various available standard parts. Recording is done on an ordinary typewriter on which the typewriter keys are operated by solenoids rather than by human fingers. The operating solenoids can be seen in the photograph directly under the typewriter keyboard at the top of the instrument cabinet. A sample of the record sheet obtained in this machine is

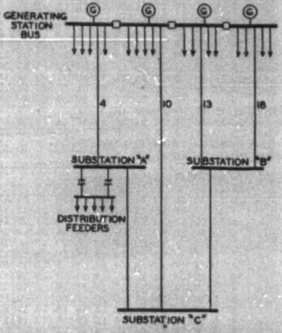

Figure 1. Typical transmission line group

The maximum loads on individual transmission lines may occur at different times due to different load characteristics on the three different substations

---

Paper 41-3, recommended by the AIEE committee on instruments and measurements and presented at the AIEE winter convention, Philadelphia, Pa., January 27-31, 1941. Manuscript submitted March 30, 1940; made available for preprinting October 26, 1940.

T. G. Le Clair is supervising development engineer for the Commonwealth Edison Company, Chicago, Ill.

The writer wishes to express his appreciation to Mr. H. M. Schaibly, whose quick perceptions and nimble fingers turned sketches and diagrams into a working machine. Appreciation is also due to Mr. J. R. Harrington and his associates for reducing the laboratory product to a flexible standardized design.

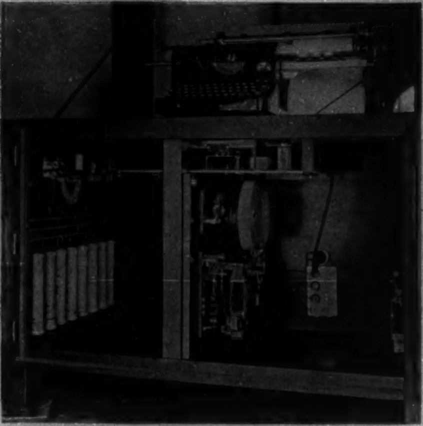

Figure 2. The first full-size automatic printing ammeter

This multicircuit printing ammeter, built in the laboratory, was the first one to record the loads on all transformers and outgoing 4,000-volt feeders of a complete substation

shown in figure 3. On this log sheet the first 12 columns of figures are the ammeter readings on each of the three phases of the four transformer banks. The remaining columns are the ammeter readings on the three phases of the outgoing 4,000 volt feeders. The spare circuit and circuit number 30 were not carrying load on the day this log sheet was taken. The figures on the log sheet are the ammeter readings in tens of amperes.

This machine, which has been in constant service for about three years, has given very satisfactory results and is adequate except for its home-made appearance. A detailed description of this printing ammeter and its method of operation will not be given in this paper because the principles are similar to those of the newer model which is appreciably more complete. The home-made instrument records the ammeter readings on 36 circuits and takes these readings every 30 minutes. At the end of the day, the log sheet for that day, in triplicate, is ejected from the machine automatically, and the log sheet for the following day is inserted ready for use.

Improved Design

After the laboratory model had been given a thorough trial in commercial operation, it was considered desirable to install a similar instrument in a generating

Figure 3. Typical log sheet from first full-size printing ammeter

station to record the ampere measurements on 45 outgoing transmission lines. However, in this station the indicating instruments are arranged in the same order on the switchboard as are the line switches on the busses in the station. The operator arranges the columns on his log sheet in the same order to avoid errors. Furthermore, the 45 lines are divided into ten different groups. The lines to a given group of load are not on adjacent switch positions, but are scattered throughout the station, as illustrated in figure 1, in order to diversify the supply to the load. This makes it necessary for the planning engineer, in using the log sheet, to look at scattered columns in order to totalize the loads in each group. Therefore, the design of the instrument was expanded to include a totalizing mechanism which records the total of the loads on the lines of each group in addition to the individual line loads.

The design was also increased in flexibility so that it would be a relatively simple matter to change the order in which the instrument readings appear on the log sheet or to change the groups of readings included in a given total. This was accomplished by the use of a plugging board arranged so that the secondary current circuits of transmission lines may be connected to the instrument in any order or grouping desired without changing any of the permanent wiring in the instrument. This is very convenient as new transmission lines are installed, or lines are cut over from one substation group to another, at intervals of a few months.

The new design also includes a printer which is designed as a part of the combined unit replacing the more cumbersome typewriter used in the early model. The result of this development is the instrument shown in the photograph, figure 4.

Parts of the Measuring Equipment

The measuring equipment in its finished form is shown in the photograph, figure 4. Figure 4*a* is a front view with the covers removed to show all of the operating parts of the equipment. Figure 4*b* is a rear view also with the cover removed, showing test switches. Each circuit to be measured is connected to a pair of these test switches, arranged so that the current circuit can be short-circuited and disconnected without disturbing any of the wiring within the instrument. The individual parts of the unit can be identified by reference to figure 5 which shows each element identified by name in the same physical position which it occupies in the photograph, figure 4*a*. For ease in describing the parts in the following method of operation, it is assumed that the current transformer ratios are 1:1 and that the instrument has a full scale reading of 100 amperes.

A contact-making clock is used to start the sequence of operations to obtain readings. This contact-making clock may be either a simple device making contact every 15, 30, or 60 minutes, or it may be set up with a definite program to take readings at variable intervals.

The master sequence switch is a rotary control switch used to determine the order in which the various functions of the instrument are performed. Each step in the process of taking measurements is controlled by this master sequence switch.

The circuit selector switch is a 50-point rotary switch with each of the circuits which are to be measured connected to one of the points or positions. A common connection leads from this switch to the measuring part of the equipment. Each circuit to be measured is normally short-circuited on itself in this selector switch but not connected to any other circuit. The circuit selector switch is used to connect each circuit in turn to the remainder of the equipment.

The balancing relay has two cores pulling at opposite ends of a balancing beam. The coil on one core is connected in turn to each circuit to be measured through the circuit selector switch; the current in this element is the current flowing in the measured circuit. The other core has two coils; each of these coils is supplied a variable current which is adjusted until the relay comes to a balance.

The measuring transformer is connected to a constant voltage a-c source and has two secondary windings to supply current to the two coils on the one core of the balancing relay through measuring switches.

The tens measuring switch is a rotary switch used to select steps on a resistor in the circuit from the measuring transformer to one coil of the balancing relay. Each step taken by this measuring switch increases the current in one coil of the balancing relay by ten amperes. Separate contacts on this measuring switch are connected to corresponding solenoid stops in the printing mechanism to select figures corresponding to the tens of amperes in the circuit.

The units measuring switch is similar to the tens measuring switch except that each step that this rotary switch takes varies the current in its corresponding coil of the balancing relay by one ampere instead of ten amperes. Separate con-

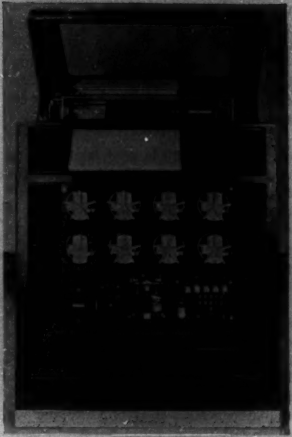

Figure 4a. Front view of standard model automatic printing ammeter

Covers have been removed to show mechanism. Printed forms feed from the front compartment through the printer mechanism at top. The typed figures on the log sheet are continuously visible through the glass cover when operating

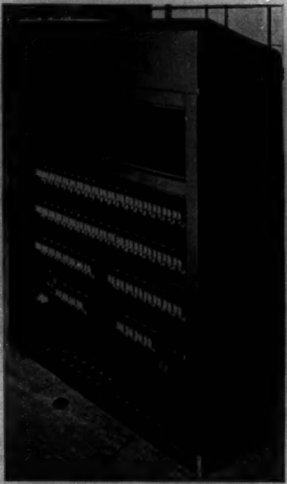

Figure 4b. Back view of standard model automatic printing ammeter

Covers have been removed to show test switches, one pair for each circuit to be measured. Completed log sheets drop into the compartment above the test switches tacts in this rotary switch are also connected to the solenoid stops in the printing mechanism.

The totalizing sequence switch is similar to the master sequence switch except that it controls the order of procedure for the printing of totals only.

Three totalizing rotary switches are used. One switch is used for totalizing units, the second one for tens, and the third for hundreds of amperes. Their method of operation is similar to that of an ordinary odometer. Each totalizing switch has contacts connected to the points in the printing mechanism to select the correct figures to be printed.

The printer consists essentially of a small type wheel which has numerals engraved on its periphery. This type wheel is caused to rotate after the instrument has struck a balance. Solenoid stops are used to position the type wheel so that the proper number is opposite the log sheet. The type wheel is then forcibly pressed against the paper and the carriage of the type wheel is shifted to the right one space ready for the next printing operation.

A number of control buttons are mounted on a panel in front of the printer. These buttons allow the operator to type line numbers at the top of the log sheet. There are also buttons for other manual control operations.

Method of Operation

An exact description of all the connections in the instrument and the method of operation would be unnecessarily long. An abbreviated description will show the essential steps in the operation without the detailed connections. The method of operation can be traced by reference to figure 6 in connection with the description. Figure 6 is a schematic or block diagram which shows each major element in relation to its place in the sequence of operations rather than in its physical position.

The numbers in parentheses inserted in the following paragraphs refer to corresponding numbers in circles in figure 6. The numbers represent the order of the steps in which the various parts of the equipment are brought into operation.

Assume that all circuits are dead and all rotary switches are in their normal or home positions. (1). The contact-making clock closes its contacts to start the taking of a reading. Through the operation of this clock and the master sequence switch the circuit selector switch connects the first circuit to be measured with one coil of the balancing relay.

The units measuring switch is first set in a position which supplies nine amperes in one coil of the balancing relay so that, if the current in the circuit to be measured is less than nine amperes, the balancing relay will trip. However, if the current in the circuit to be measured is greater than nine amperes, nothing happens.

(2). The master sequence switch through the balancing relay next starts the tens measuring switch to rotate. Each step that this switch takes increases the current in the corresponding coil of the balancing relay by 10 amperes, so that the corresponding total pull on the relay is successively 9 amperes, 19 amperes, 29 amperes, etc., until the balancing relay trips. For example, assume the current to be measured is 36 amperes. In this case the relay trips in the third position when the pull of 39 amperes overcomes the pull of 36 amperes. The tens totalizing switch is driven synchronously with the tens measuring switch, but no connection is made from the totalizing switch to the printer at this time. (3). The tripping of the balancing relay completes a circuit through the second group of contacts on the tens measuring switch to select the correct solenoid stop on the printing mechanism to print on a log sheet the number corresponding to the tens of amperes measured (in the example, the number 3).

(4). The master sequence switch transfers the operation to the units measuring switch. The units measuring switch is first placed in the position of zero current in the units coil so that the balancing relay then has a total current less than that in the circuit to be measured. (In the example 30 amperes.) The units measuring switch then rotates, increasing the current in its corresponding coil one ampere at each step until the balancing relay again trips. The units totalizing switch also operates synchronously with the units measuring switch but does not operate the printer. (5). The tripping of the balance relay then selects through the separate contacts of the units measur-

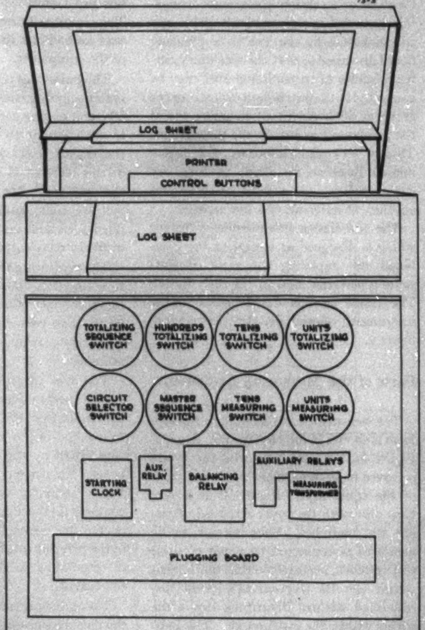

Figure 5. Outline sketch of printing ammeter

Outline sketch of front view in figure 4a on which each unit of the equipment has been labeled for identification

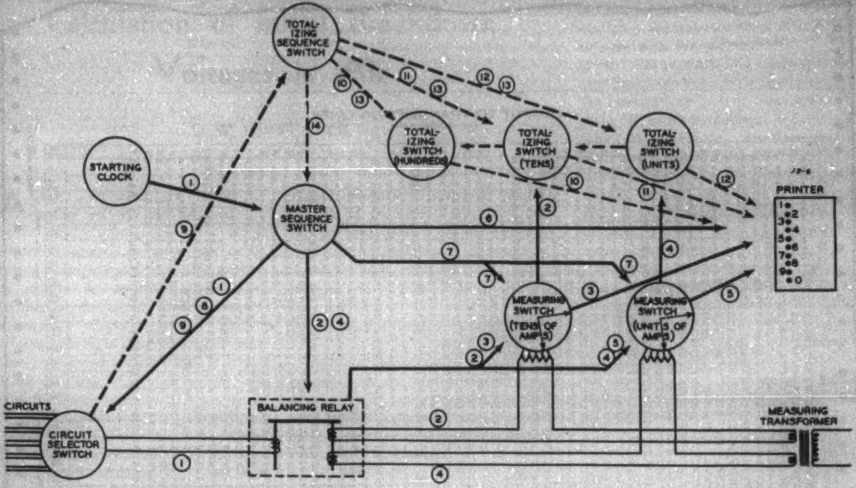

Figure 6. Block diagram for operating sequences of the instrument

Same elements are shown as in figure 5, except that elements are shown in relation to their sequence in the operation of the instrument and not in their physical position. Small numbers in circles refer to the order in which the steps are taken in the process of recording instrument readings. These numbers correspond to numbers in the description in the text

ing switch the correct solenoid stop on the printing mechanism to print the figure corresponding to the units of amperes measured (in the example, the number 6). (6). Then the master sequence switch operates the printer to space the carriage ready for the next reading.

(7). The master sequence switch next restores the tens and units measuring switches to the home position. However, the totalizing rotary switches are not restored to the home position at this time, but remain as set by the first reading.

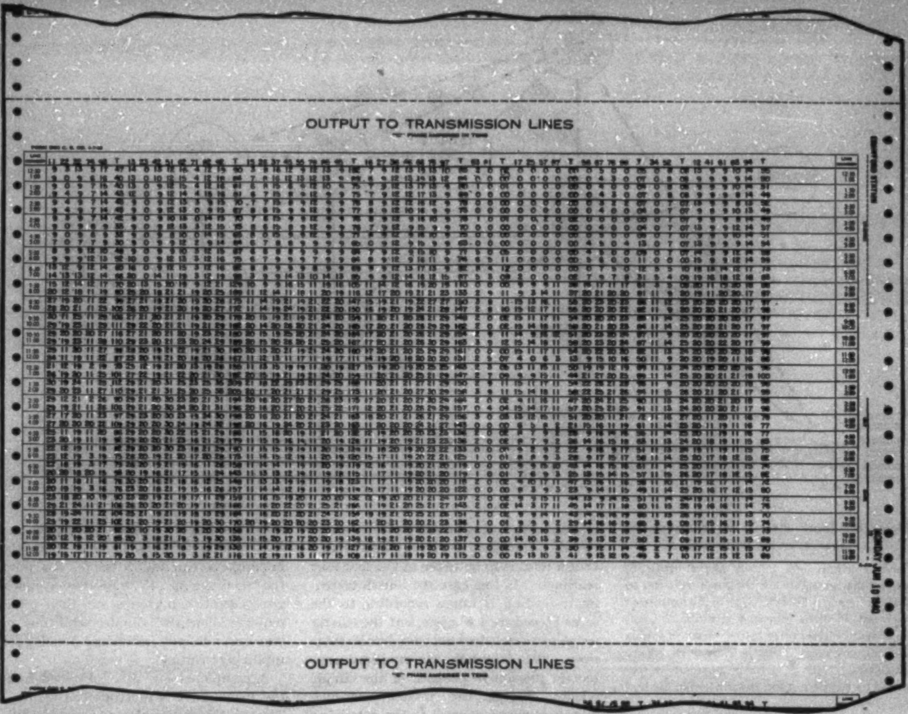
The steps just described complete the cycle of operation for taking and printing the instrument reading for one circuit. (8). The master sequence switch next advances the circuit selector switch one step in order to disconnect the first measured circuit from the balancing relay and connect the second circuit to be measured to the balancing relay. The operation of measuring and printing is repeated for the second circuit exactly as for the first.

The circuit selector switch is equipped with separate contacts by means of which a total reading can be taken after the instrument reading on any predetermined circuit. For example, it may be assumed that a total is to be taken of the first four readings. In this case the fourth instrument reading is taken according to the same procedure as before, but the master sequence switch does not complete its rotation. (9). Through the auxiliary contact in the fourth position of the circuit selector switch the master sequence switch transfers control to the totalizing sequence switch. The totalizing sequence switch then connects to the printer in turn the (10) hundreds, (11) tens, and (12) units totalizing switches to record the positions of the dials, which correspond to the total of the figures printed for the first four instrument readings. (13). The totalizing sequence switch then returns the three totalizing switches to the normal or home position and (14) transfers control back to the master sequence switch to complete its travel and go on with the next reading.

Additional equipment which is relatively simple and not shown on the block diagram is used to return the printer carriage to the home position, advance the log sheet one line for the next reading, and de-energize the instrument at the end of a complete set of readings. Other auxiliary equipment is also used to eject one log sheet from the printing ammeter and insert a new one at the end of a specified period when the log sheet is filled.

This description of the sequence of operation may create an illusion as to the length of time required for a complete set of readings. Actually the relays and switches operate much faster than the human eye can follow them. To print the readings of 45 transmission lines, grouped into ten groups, and their totals requires about two minutes total time, or two seconds per individual reading or totalizing printing.

A completed log sheet obtained from the instrument is illustrated in figure 7. The printing mechanism types across this log sheet every 30 minutes and at the end of the reading advances the sheet automatically to the next line. The right-hand and left-hand columns of figures on the printed form are the hours of the day at which each row of instrument readings was recorded. The typed numbers in the top row are the numbers of the outgoing transmission lines and the numbers below these column headings are the ampere readings in ten's on each line. The letter "T" above a column represents the column of totals for the group of line readings directly to the left of this column. For example, the first total is of the ampere readings on line numbers 11, 22, 32, 74, and 93. The picture shows also the top of the form for the following day. When the sheet is advanced automatically at the end of the day, the next form is ready for the first reading at 12:30 a.m. and the log for the day can be torn off at the perforations. In unattended substations the continuous forms can accumulate for several days in the compartment back of the printer until an operator arrives to remove them.



OUTPUT TO TRANSMISSION LINES

OUTPUT TO TRANSMISSION LINES

Figure 7. Typical log sheet obtained from the automatic printing ammeter

Photograph shows the log sheet for one day with the bottom edge of the log sheet for the preceding day and the top of the sheet for the following day above and below the perforated lines on the continuous form. Column headings are the numbers of the outgoing transmission lines

The complete printing ammeter contains a number of relay contacts. However, not many of these contacts are involved in a particular operation. The printing ammeter shown in figure 2 has been in regular operation for about three years and has been nearly free of trouble since the initial period when it was subject to frequent tampering for the benefit of curious visitors. The instrument shown in figure 4 has been in service nearly a year. It appears that the maintenance costs on one printing ammeter for a multiplicity of lines will compare very favorably with the maintenance cost on a number of indicating ammeters, one for each line.

Fields of Usefulness

One of the major fields in which this device is very useful is in automatic or supervisory control substations. In such substations the installed cost of this multiple-circuit instrument should approximate the installed cost of individual instruments on each circuit. For such installations a traveling operator has only one instrument from which to remove records. The single record sheet is much more convenient to handle, mail, and file, than a large number of graphic instrument charts containing similar information.

In generating stations or larger substations which are attended, the elimination of the human element results in a more accurate and more legible record. All readings are taken on scheduled time as determined by the clock contacts whether or not the operator is interrupted by the telephone or other operating duties. In busier galleries there may be a saving of labor.

The instrument can be made in more portable form so that it can be used for special tests or for periodic routine load checks if desired. The plugging board, similar to a telephone switchboard, makes it relatively simple to connect circuits in any desired order for special test purposes.

For any of these applications, the instrument is appreciably more accurate than the standard switchboard type of instrument. In a device such as this where only one measuring element is used for a multiplicity of circuits, it is economical to have not only a more accurate, but a more rugged measuring element. The laboratory model of the instrument has been in service about three years, during which time the measuring element has been dismantled and put back together for check, and it has not required any recalibration to maintain an accuracy of plus or minus one per cent.

Where records are used in more than one office for various purposes, the instru-

Calculation of Initial Breakdown Voltages in Air

D. W. VER PLANCK
ASSOCIATE AIEE

ALTHOUGH spark-over and corona starting voltages can be predetermined satisfactorily in cases for which empirical formulas or curves are available, a more generally applicable method is needed. An approach to such a method is through a modification of Townsend's theory[1,1a] which, though possibly lacking in rigor, suffices in many cases for the accurate calculation of breakdown voltages. Calculations of this kind by Schumann[2] in 1923 for air in nonuniform fields were not entirely successful because of inadequate knowledge of the Townsend coefficients for air, a deficiency now remedied.[3,4,5] Loeb has discussed the modified Townsend theory at length and has applied it quantitatively to nitrogen in uniform fields.[6,7,8a]

The present paper outlines the theory and shows that the initial breakdown voltage may be calculated using two quantities characteristic of the gas for cases where the field, if nonuniform, converges toward the cathode. Formulas expressing one of the characteristic quantities for air, the Townsend coefficient α, are assembled, and a formula for the second quantity is deduced from an analysis of published spark-over gradients for plane gaps. The method is applied to two cases and the results are shown to be in agreement with experiment

Fundamental Considerations

Electrical breakdown of a gas depends primarily on the presence of free electrons. Their concentration, normally very small, is determined by the relative activity of the ionizing agents, radioactive emanations for instance, and the effects which cause them to disappear. Besides recombining directly with positive ions, the free electrons may be swept away by an applied field, and in air they may form negative ions by attachment to neutral oxygen molecules.

In an electric field, the electrons may gain sufficient energy to excite or ionize molecules in their paths. When the gradient exceeds 15 kilovolts per centimeter in atmospheric air, the electrons are more likely to ionize than to become attached to oxygen molecules. Then each electron as it travels toward the anode continues to make ionizing collisions, liberating more electrons which in turn multiply similarly. A single electron set free by an external agent can thus initiate an *electron avalanche* consisting of a cluster of electrons which grows rapidly as it advances and which leaves a trail of positive ions. With the field strength occurring at breakdown, an avalanche has a velocity of the order of 10^7 centimeters per second, while the positive ions left in the trail move back toward the cathode with but a hundredth of this speed. The negative ions resulting from attachment of electrons to molecules and the positive ions cannot gain sufficient energy to ionize by collision in fields attained at breakdown. The ions generated by a single avalanche disappear quickly, causing merely a small pulse of current, and the passage of a single or even many separate avalanches from cathode to anode does not necessarily result in breakdown.

There are, however, *secondary mechanisms* by which an avalanche can cause the liberation outside itself of electrons which may start new avalanches. If each avalanche initiated causes the release of at least one secondary electron in a favorable location, a self-sustaining discharge current, that is breakdown, can result from the liberation of a single electron by an external agent. The exact nature of the secondary mechanisms active in given circumstances remains a matter for speculation[8a] but a few generalizations are safe.

Two kinds of breakdown are recognized which, though they may merge, are distinct as to secondary mechanisms believed to be active. One, the *cathode initiated type*, occurs in the corona around negative electrodes and in the normal or static spark-over of short gaps. In it, positive ion bombardment or radiation from molecules excited by the avalanche causes emission of secondary electrons from the cathode surface. The other type, of which the lightning leader stroke is a manifestation, is the *positive streamer*, and occurs in the corona around positive electrodes, in the normal spark-over of long gaps, and in short gaps when more than the initial breakdown voltage is very suddenly applied. The secondary mechanism for this type is more complicated and probably involves photoelectric action in the gas and intensification of the

---

ment will produce four or five good carbon copies. In the Chicago substation three copies of the record are made, one for the operating department, one for the substation load record, and one for the distribution feeder load record. In the generating station four copies are made.

The printer need not be installed in the same cabinet with the measuring equipment. It is practicable to locate the measuring equipment near the control wiring and have the printer make the record sheet in a different room.

The present instrument is confined to ampere readings. However, it will probably be extended to other quantities such as volts or watts when the need arises.

The totalizer element of the instrument was a relatively inexpensive addition. It proved to be a valuable time saver for planning engineers because it eliminated the need of totalizing the figures in scattered columns. The hour of maximum load is obtained by scanning the total column only, and load analysis is usually made for only the maximum load.

Conclusion

This new automatic printing ammeter produces a compact record of the load on any number of circuits up to 50, with readings arranged in the form of a column for each circuit and a line for each hour of the day. The load record also includes totals for groups of lines. The following are incidental benefits derived from the use of the instrument: greater accuracy, greater legibility, duplicate records, and uniform timing of readings.

field by the space charge of successive avalanches.

This paper is concerned only with the calculation of the voltage at which cathode initiated breakdown occurs, and the question of whether the initial breakdown is a complete spark-over or a stable corona discharge is not considered.

The Townsend Coefficient α

The number of electrons n comprising an avalanche increases with distance s along the path at a rate proportional to the number already present. Thus

$$\frac{dn}{ds}=\alpha n \qquad (1)$$

where α, the Townsend coefficient, is dependent on the field strength as well as the density and kind of gas. The path of the avalanche is a line of electrostatic force if the gas density is high enough so that the electron mean free path is small compared to the radius of curvature of the field line, a condition likely to be true in practice. For an avalanche initiated by a single electron from the cathode, $s=0$, integration along a line of electrostatic force gives for the number of electrons when the avalanche reaches the anode, $s=S$,

$$n=\epsilon^{\int_0^S \alpha ds} \qquad (2)$$

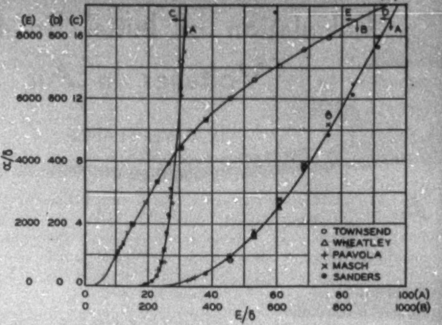
where α through its dependence on field strength is a function of s. The number of positive ions left in the trail of the avalanche is practically equal to n, although accurately it is one less since the initiating electron was emitted from the cathode.

If the avalanche grows large enough, the space charge of the ions causes the field to vary within the avalanche so that α is not the same for all of the electrons, and equation 2 is no longer true. However, certain calculations,[9] too lengthy to be included here, indicate that the field distortion caused by a single avalanche is negligibly small in a wide range of practical cases.

The method of measuring α, originated by Townsend,[1b] is based on the application of equation 2 to the continual succession of avalanches initiated by a current of photoelectrons emitted from the cathode of a parallel plane gap. Townsend found that α is related to field strength E and gas density δ by $\alpha/\delta=F(E/\delta)$ where the function F depends on the kind of gas.[1c]

Townsend,[1c,2b] Wheatley,[2b] Paavola,[4a] Masch,[5] and Sanders[3] have determined α for air with the results shown in figure 1. In this paper E is in kilovolts per centimeter and δ is the density relative to that at 760 millimeters and 25 degrees centigrade, units more convenient for calculations on atmospheric discharges than those employed by physicists, which are respectively volts per centimeter and millimeters of mercury. Density is used rather than pressure because mean free path, the significant factor, depends on density in general but on pressure only at constant temperature.

Figure 1. The Townsend coefficient α for air



The curves in figure 1 are plotted using the following empirical formulas which serve to express α for air in the ranges of E/δ indicated.

$$\left.\begin{array}{l}
\text{Range I.}\quad 15<E/\delta<25.8\\
\alpha/\delta=a_1\epsilon^{b_1E/\delta}\\
\quad a_1=1.67\times10^{-5}\\
\quad b_1=0.47\\
\text{Range II.}\quad 25.8<E/\delta<78.7\\
\alpha/\delta=a_2(E/\delta-b_2)^2\\
\quad a_2=0.166\\
\quad b_2=21.5\\
\text{Range III.}\quad 78.7<E/\delta<200\\
\alpha/\delta=a_3(E/\delta-b_3)\\
\quad a_3=19.0\\
\quad b\;=50.0\\
\text{Range IV.}\quad 200<E/\delta<467\\
\alpha/\delta=a_4\epsilon^{-b_4\delta/E}\\
\quad a_4=1.08\times10^4\\
\quad b_4=266\\
\text{Range V.}\quad E/\delta>467\\
\alpha/\delta=a_5(E/\delta)^{1/2}-b_5\\
\quad a_5=322\\
\quad b_5=850
\end{array}\right\} \qquad (3)$$

Formulas for α similar in form to the first, second, fourth, and fifth of these have been given by Sanders,[3] Paavola,[4b] Townsend,[1d] and Loeb[6a] respectively, but here the constants have been adjusted for agreement with all of the data. The formulas result in curves tangent to each other at the given limits, so that for convenience in calculation the limits may be shifted slightly without serious loss of accuracy.

For $E/\delta<15$ it is assumed that $\alpha/\delta=0$; it is certainly less than 0.02, the value at $E/\delta=15$.

Cathode Initiated Breakdown

In cathode initiated breakdown a single electron released by an external ionizing agent starts an avalanche from the cathode surface. As this avalanche crosses the gap, the secondary mechanisms come into play and if they release at least one electron from the cathode, one or more new avalanches may follow. When the secondary mechanisms are sufficiently active to assure the continued repetition of this process without further action by the external agent, breakdown results.

One of the two important mechanisms by which an avalanche can cause electron emission from the cathode is through bombardment by the positive ions left in the trail. The probability that a positive ion striking the cathode will cause an electron to be released is a function of the kind of surface and the energy of the impinging positive ion. The mean free path being small, the energy for a given gas is proportional directly to the gradient E_c at the cathode surface and inversely to the density of the gas; that is, to the ratio E_c/δ. The probability that a released electron will escape diffusion back to the cathode or attachment to a neutral molecule and be able to start an avalanche also depends on E_c/δ.[4b] Thus the number N of positive ions which must strike the cathode to assure the initiation of one secondary avalanche is a function of E_c/δ and is independent of gap geometry. The condition for breakdown is that the number of positive ions left in the trail of the original avalanche must equal or exceed the number N; that is, with the aid of equation 2,

$$\epsilon^{\int_0^S \alpha ds}\geq N \qquad (4)$$

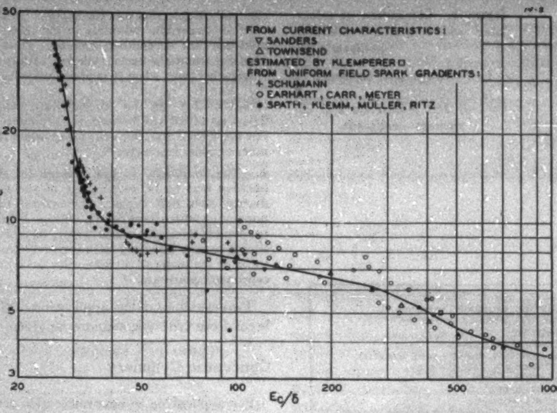


Figure 2. Log$_e$ N for air

a criterion given in the literature in various equivalent forms.[16,8c,8a]

The other important mechanism for the release of secondary electrons at the cathode is through photoelectric action of radiation from molecules excited by the avalanche.[8d] It will now be shown that equation 4 applies approximately for this process also. The number of molecules excited by the impact of electrons is roughly proportional to the number ionized,[8d] hence the total radiation from the trail of an avalanche is proportional to the number of positive ions formed, exp $(\int_0^S \alpha ds)$. Radiation reaching the cathode surface has its greatest intensity near the starting point of the avalanche, this being nearest to all parts of the trail because the avalanche path, a line of force, necessarily starts normal to the cathode surface and in practical cases never curves sharply. For a given cathode gradient and avalanche size, the intensity of radiation at the cathode should depend on the variation of gradient with distance from the cathode because this would affect the distribution of excited molecules along the avalanche trail. However, this effect of gap geometry is probably not great and is neglected here. The number of electrons released per unit of radiation reaching the cathode depends on the properties of the surface, and as before the probability that an electron will escape attachment or diffusion back to the cathode and be able to start a new avalanche depends on E_c/δ. Thus, as with positive ion bombardment, the probability that a secondary avalanche will be initiated is a function of E_c/δ and is proportional to the number of positive ions formed by the original avalanche, and consequently equation 4 is also the criterion for breakdown by the photoelectric mechanism.

With either mechanism the secondary avalanches are most likely to be initiated near the starting point of the original avalanche, for this part of the cathode is both where the positive ions strike and where the radiation is most intense. The two mechanisms may act jointly but evidence that the time lag for spark formation in uniform fields is less than the gap transit time for a positive ion makes the photoelectric mechanism more likely,[8e] although for corona on small negative wires, positive ion bombardment probably predominates.[7]

The Number N for Air

The criterion 4 implies that breakdown occurs when exp $(\int_0^S \alpha ds)$, the number of electrons in an avalanche which has crossed the gap, equals or exceeds N, a number characteristic of the gas and dependent on the cathode gradient to density ratio E_c/δ, but independent of the type of field.

To obtain a knowledge of N for air, equation 4 was applied as the criterion for a spark in uniform field, when if the gap length is S the relation

$$\log_e N = \alpha S \quad (5)$$

follows at once. Here the right member can be determined for any value of E/δ with the aid of the empirical formulas 3 for α/δ and abundant information in the literature relating the quantities $S\delta$ and E/δ for sparks in uniform fields. In this way N can be determined for a wide range of E_c/δ, since in this case E_c and E are identical. The data used were the well known curve by Schumann[30] based on a survey of the work done prior to 1922; results by Earhart,[8d] Meyer,[29] and Carr[1f] which fall outside the range of Schumann's curve; and results obtained since 1922 by Spath,[10] Klemm,[11a] Müller,[12a] and Ritz.[13]

In figure 2 log$_e$ N has been plotted rather than N because it is the former that is desired for general use. While the points show considerable dispersion, a mean curve can be determined with fair certainty. This curve is expressed in the range $26<E_c/\delta<250$ by the empirical formula

$$\log_e N = 10.0(25\delta/E_c)^{0.3} + 43.0(25\delta/E_c)^{9.6} \quad (6)$$

The last term is negligible when $E_c/\delta>60$.

When positive ion bombardment is the predominant secondary mechanism, the reciprocal of N is identical with the probability γ that a positive ion impact will release an electron from the cathode. A few values of γ for air obtained from prebreakdown current characteristics are reported by Sanders,[2] and a few others may be calculated from similar data by Townsend.[16] Points obtained from these and from an estimate of γ attributed to Klemperer[14] are included in figure 2.

Application of the Breakdown Criterion

For the calculation of initial breakdown voltages the criterion 4 is more convenient in the equivalent form

$$\int_0^S \alpha ds \geq \log_e N \quad (7)$$

The greater the inequality, the more nearly certain is breakdown, but since the left member turns out to be a function which increases very rapidly with applied voltage, the equality may be taken for practical purposes as the criterion for breakdown to be certain.

The left member of equation 7 depends on the field intensity E at every point along a line of force between the electrodes, and the right on the intensity E_c at the cathode end of this line. The field intensity, given by electrostatic theory, is proportional at every point to the voltage between electrodes if the field distortion caused by single avalanches is neglected and if no other space charges are present. Thus equation 7 gives the voltage implicitly or, if desired, the gradient at any point such as the cathode, at which breakdown will occur along the line of force considered. The breakdown voltage for

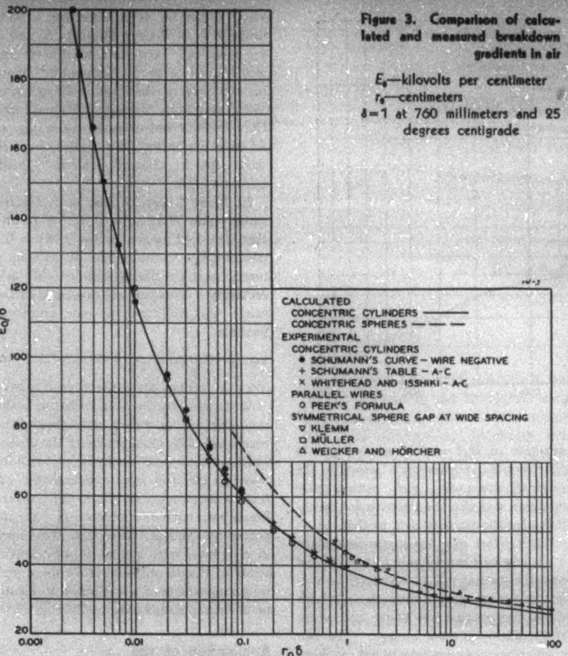

Figure 3. Comparison of calculated and measured breakdown gradients in air

E_0—kilovolts per centimeter
r_0—centimeters
$\delta = 1$ at 760 millimeters and 25 degrees centigrade

a given gap is found from the line of force for which equation 7 gives the lowest voltage. In many practical cases the proper line can be selected by inspection as the shortest one.

The integration corresponds to the entire growth of an avalanche, and consequently in general is from the cathode $s=0$ along a line of force, to the anode $s=S$. However, in air if the field diverges from the cathode to such an extent that E/δ becomes less than 15 before the anode is reached, the upper limit may be taken at the point where $E/\delta=15$, because $\alpha=0$ for $E/\delta<15$.

Special consideration is necessary if the field converges again beyond a region where $E/\delta<15$. At the lower field intensities, $E/\delta<15$, the electrons are more likely to become attached to oxygen molecules than they are to ionize by collision. With no field applied, the electrons survive on the average during the motion of thermal agitation only about ten collisions with oxygen molecules before becoming attached.[18] Moreover, the electrons do not become detached from negative ions when E/δ is less than about 70.[8b] Then since negative ions do not ionize by collision in fields normally attained, an avalanche having passed through a region of appreciable extent where $E/\delta<15$ would not grow further unless it passed into a region where $E/\delta>70$. In such cases equation 7 is not directly applicable.

The breakdown criterion, equation 7, is applicable to impulse as well as to direct voltages, provided that:

1. An adequate supply of initiating electrons is maintained by the external ionizing agents.

2. The applied voltage does not change appreciably during the extremely brief time of transit of the avalanche. In the case of sphere-gaps the impulse breakdown voltage is the same as the static value if the time from the zero of voltage to the crest exceeds about two microseconds.[16]

The criterion also gives the crest value of alternating voltage at which breakdown will occur with a given electrode considered as cathode, provided in addition that:

3. Breakdown has not already occurred during the previous half cycle when the electrode in question was the anode. In the case of concentric cylinders in air there is evidence that breakdown occurs at a lower gradient when the inner cylinder, radius r_0, is negative than when it is positive for $r_0\delta<0.01$ and for $r_0\delta>0.19$ and at least up to $r_0\delta=7.0$.[2f,17,18] In the intermediate range $0.01<r_0\delta<0.19$ the breakdown gradient is not more than four per cent lower when the inner cylinder is positive.[2f]

4. The frequency is low enough for the positive ions to be swept clear of the gap during each half cycle. The critical frequency at which breakdown voltage begins to depart from its static value has been shown to vary inversely with gap length and to be of the order of 50 kilocycles for a one centimeter plane gap.[19]

Two examples of the application of the breakdown criterion will now be given.

Concentric Cylinders

For application to concentric cylinders the inner of which is negative, the breakdown criterion, equation 7, is expressed in terms of the radius r, the co-ordinate along a line of force. Thus

$$\int_{r_0}^{r_1} \alpha dr = \log_e N \tag{8}$$

where r_0 and r_1 are respectively the radii of the inner and outer cylinders. The right member is a function of the cathode gradient which in this case is the gradient E_0 at the inner cylinder.

Because α is a function of the field intensity E, it is convenient to change the variable of integration from r to E by means of the relation $E=E_0r_0/r$ for the field between concentric cylinders. Equation 8 then becomes

$$\int_{E_0}^{E_0r_0/r_1} \alpha(-E_0r_0E^{-2}dE) = \log_e N \tag{9}$$

Then

$$r_0 = \frac{\log_e N}{E_0 \int_{E_0r_0/r_1}^{E_0} \alpha E^{-2} dE} \tag{10}$$

which for any given ratio of radii, r_0/r_1, relates the radius r_0 of the inner cylinder to the gradient E_0 at which a negative discharge will start.

The integral can be evaluated graphically as the area under a curve derived directly from α figure 1, or analytically, using the empirical formulas 3 for α as is done in appendix *A*.

An important case is where the outer cylinder is quite large compared to the inner. When it is large enough so that at its surface $E/\delta<15$, that is $r_1>(E_0r_0/15\delta)$, α is zero in the space adjacent to the outer cylinder and the integration can be started at $E=15\delta$ instead of at $E=E_0r_0\div r_1$, making the result independent of r_1.

In this case when the integrals from appendix *A* and numerical coefficients from the formulas 3 and 6 are substituted in equation 10 and the result arranged for easy computation, there is obtained for E_0/δ between 25.8 and 78.7

$$r_0\delta=\frac{10.0\left(\frac{25\delta}{E_0}\right)^{1.2}+43.0\left(\frac{25\delta}{E_0}\right)^{10.6}}{0.226+103.75\left(\frac{E_0}{25\delta}-1\right)-178.45\times\log_e\left(\frac{E_0}{25\delta}\right)+76.73\left(1-\frac{25\delta}{E_0}\right)} \quad (11)$$

and for E_0/δ between 78.7 and 200

$$r_0\delta=\frac{7.92\left(\frac{80\delta}{E_0}\right)^{1.2}}{236.8+1{,}520\log_e\left(\frac{E_0}{80\delta}\right)-950\left(1-\frac{80\delta}{E_0}\right)} \quad (12)$$

The results of theory and of experiment are compared in figure 3. The solid curve is a plot of equations 11 and 12. The experimental points are from a curve by Schumann,[3f] based on work of Farwell, Schaeffers, Whitehead and Brown, and Whitehead and Lee; from a table by Schumann[3g] based on researches by himself, Peterson, and Peek; from empirical formulas by Whitehead and Isshiki[17]; and from the empirical formula for parallel wires by Peek.[20] Excepting the last, all of the data are for concentric cylinders, and for either a negative inner cylinder or alternating voltage. The greatest departure of any point from the curve is about four per cent, and at that place there are other points on the opposite side. Thus the theoretical curve is in substantial agreement with experiment throughout a range of $r_0\delta$, the extremes of which are in a ratio of about 6,000 to 1.

An empirical formula often used to correlate corona starting gradients for cylinders is of the type

$$E_0/\delta=A+B(r_0\delta)^{-1/2} \quad (13)$$

where *A* and *B* are constants which have been given various values.[17,20] A plot of E_0/δ against $(r_0\delta)^{-1/2}$ as calculated from equations 11 and 12 shows some deviation from the form of equation 13, for as shown in figure 4, instead of having a constant value *B*, the slope first decreases considerably and then increases very slightly. Equation 13 thus does not agree with the theory although it may serve as a very convenient approximation over limited ranges.

Concentric Spheres

The breakdown criterion, equation 7, written for concentric spheres is identical with equation 8 except that *r* is the spherical instead of the cylindrical radius. Letting E_0 be the gradient at the surface of the inner (negative) sphere of radius r_0, the gradient at radius *r* is given by $E=E_0(r_0/r)^2$ from which it follows that

$$dr=-\frac{r_0E_0^{1/2}dE}{2E^{3/2}} \quad (14)$$

Substituting this in equation 8 and solving for r_0:

$$r_0=\frac{2\log_e N}{E_0^{1/2}\int_{15\delta}^{E_0}\alpha E^{-3/2}dE} \quad (15)$$

In making the lower limit of the integral 15δ, it is assumed that the region of ionization does not extend to the outer (positive) electrode.

The integral must be separated into parts corresponding to the ranges of α formulas 3, and when the integrations are carried out as shown in appendix *B*, there results for the case where E_0/δ is between 25.8 and 78.7

$$r_0\delta=\frac{10.0\left(\frac{25\delta}{E_0}\right)^{0.7}+43.0\left(\frac{25\delta}{E_0}\right)^{10.1}}{0.1049+34.58\left[\left(\frac{E_0}{25\delta}\right)^{3/2}-1\right]-178.45\times\left[\left(\frac{E_0}{25\delta}\right)^{1/2}-1\right]+76.73\left[1-\left(\frac{25\delta}{E_0}\right)^{1/2}\right]} \quad (16)$$

This result is plotted as the dashed curve in figure 3. The experimental points shown, taken from curves presented by Klemm,[11b] Müller,[12b] and Weicker and Hörcher,[21] are the limiting breakdown gradients approached at wide spacings in the symmetrical gaps between equal spheres at potentials equally above and below ground.

The justification for comparing results measured for symmetrical sphere-gaps with those calculated for concentric spheres, as well as for including experimental points for parallel wires with the curve calculated for concentric cylinders, is as follows:

1. As the spacing of the symmetrical gap is increased, the field in the region surrounding the negative electrode where the ionization occurs approaches that for concentric electrodes.
2. The electrons passing into mid gap where the field is weak become attached to neutral molecules forming negative ions which cannot ionize by collision as they go on into the intense field around the positive electrode.

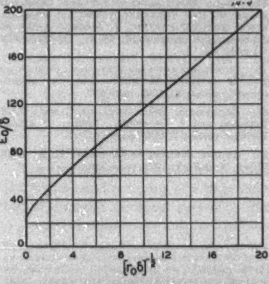

Figure 4. Calculated results for concentric cylinders tested for agreement with empirical formula of the type $E_0/\delta=A+B(r_0\delta)^{-1/2}$

Conclusion

The initial breakdown voltages for two distinct types of nonuniform field have been calculated accurately by means of the breakdown criterion, equation 7, and the data contained in formulas 3 and 6, for as shown in figure 3 the results are in excellent agreement with experiment. In addition to the two examples given here, the method is being applied to breakdown between sharp edged electrodes, and it is hoped to present the results when the experimental confirmation is complete.

For the successful application of the method it is fortunate that the voltage calculated from equation 7 is relatively insensitive to changes in *N* because this quantity depends on mechanisms whose exact nature is somewhat obscure. Consequently the agreement of theory and experiment shown in figure 3 is not offered as proof of the correctness of the physical picture used in developing the method. There is evidence[8a] that in plane gaps where $S\delta>0.3$, which corresponds approximately to $E_0/\delta<35$, breakdown is not cathode initiated as assumed here but proceeds by streamer formation. However, as may be seen in the lower right hand portion of figure 3, the method yields correct results when $E_0/\delta<35$ in spite of the possible lack of rigor in this range.

Finally it should be noted that while the data presented pertain to breakdown in air, the method is general and applicable to any gas for which the characteristic quantities α and *N* are known.

Appendix A—Integration for Concentric Cylinders

The integral in equation 10 must be separated into parts corresponding to the ranges in which the formulas 3 for α apply. The extreme limits of integration are the gradients at the outer and inner cylinders, while the intermediate limits of the partial integrations are the limits of the ranges of α.

The number of ranges which must be included depends on the case considered.

When the gradient at the outer cylinder is less than 15δ and unless the inner cylinder is extremely large, the integration must go completely through range I and terminate in ranges II or III. For range I

$$a_1\delta\int_{15\delta}^{25.8\delta}\epsilon^{b_1E/\delta}E^{-2}dE=-a_1\epsilon^{b_1E/\delta}\delta/E\Big]_{15\delta}^{25.8\delta}+$$

$$b_1a_1\int_{15\delta}^{25.8\delta}\epsilon^{b_1E/\delta}E^{-1}dE$$

$$=-a_1\epsilon^{b_1E/\delta}\delta/E\Big]_{15\delta}^{25.8\delta}+$$

$$b_1a_1[\overline{\mathrm{Ei}}(25.8b_1)-\overline{\mathrm{Ei}}(15b_1)] \qquad (17)$$

where the exponential integral function $\overline{\mathrm{Ei}}$ is defined and tabulated by Jahnke and Emde.[22a]

The integration in range II is

$$a_2\delta\int_{25.8\delta}^{E_0}(E/\delta-b_2)^2E^{-2}dE=$$

$$a_2[E/\delta-2b_2\log_\epsilon(E/\delta)-b_2^2\delta/E]_{25.8\delta}^{E_0} \qquad (18)$$

For very small inner cylinders the integration must go beyond range II. Then the upper limit of 18 becomes 78.7δ instead of E_0 and integration into range III is necessary.

$$a_3\delta\int_{78.7\delta}^{E_0}(E/\delta-b_3)E^{-2}dE=$$

$$a_3[\log_\epsilon(E/\delta)+b_3\delta/E]_{78.7\delta}^{E_0} \qquad (19)$$

Appendix B—Integration for Concentric Spheres

The integral in equation 15 must be separated into parts corresponding to the ranges in which the formulas 3 for α apply. Treating only the case where E_0 is in range II, the entire contribution of range I is

$$a_1\delta\int_{15\delta}^{25.8\delta}\epsilon^{b_1E/\delta}E^{-3/2}dE=$$

$$-2a_1\delta\epsilon^{b_1E/\delta}E^{-1/2}\Big]_{15\delta}^{25.8\delta}+$$

$$2a_1b_1\int_{15\delta}^{25.8\delta}\epsilon^{b_1E/\delta}E^{-1/2}dE$$

$$=-2a_1\delta\epsilon^{b_1E/\delta}E^{-1/2}\Big]_{15\delta}^{25.8\delta}+4a_1(b_1\delta)^{1/2}\times$$

$$\int_{\sqrt{15b_1}}^{\sqrt{25.8b_1}}\epsilon^{Z^2}dZ \qquad (20)$$

where the last integral is obtained through the substitution $(b_1E/\delta)=Z^2$. Since values of this integral are available[22b] only for the range of limits 0 to 2, while the limits here are approximately 2.7 and 3.5, it is necessary to resort to a series[23] for computation.

For range II:

$$a_2\delta\int_{25.8\delta}^{E_0}(E/\delta-b_2)^2E^{-3/2}dE=$$

$$a_2\delta^{1/2}\Big[(2/3)(E/\delta)^{3/2}-4b_2(E/\delta)^{1/2}-$$

$$2b_2^2(\delta/E)^{1/2}\Big]_{25.8\delta}^{E_0} \qquad (21)$$

List of Symbols

In all cases electric field strengths are in kilovolts per centimeter and lengths are in centimeters.

$a_1 \ldots a_6$,
$b_1 \ldots b_6$ = Empirical factors in formulas 3 for α
E = Field strength
E_c = Field strength at the cathode surface
E_0 = Breakdown gradient at inner cylinder or sphere
F = Function relating α/δ to E/δ; expressed for air by formulas 3
N = Number of electrons in an avalanche which has crossed the gap at the breakdown voltage, a function of E_c/δ expressed for air by the empirical formula 6
n = Number of electrons in an avalanche
r = Radial co-ordinate
r_0 = Radius of inner cylinder or sphere
r_1 = Radius of outer cylinder or sphere
S = Distance from cathode to anode along the avalanche path, a line of force
s = Co-ordinate of avalanche center measured from the cathode along a line of force
α = The Townsend coefficient for ionization by electron impact; the number of electrons added to an avalanche per centimeter of travel per electron already present (centimeters)$^{-1}$
γ = The probability that a positive ion striking the cathode will release an electron
δ = Relative air density; unity for 760 millimeters and 25 degrees centigrade

Picture Transmission by Submarine Cable

J. W. MILNOR
FELLOW AIEE

Synopsis: The direct transmission of pictorial matter over transatlantic submarine cable has become practical through the development of some special types of networks and amplifiers. These are required because of the rapid increase of the circuit attenuation with frequency, and in order to override certain characteristic electrical interference to which the cable is subject. A summary is presented of the fundamental theory which governs facsimile and telegraph transmission, and the methods are shown by which this is applied to meet the conditions of cable picture working.

AN efficient system for transmission of facsimile matter from London to New York by submarine cable was made available to the public in April 1939. This provides an important advantage over radio sending of pictorial subjects, in that the cable system is not subject to unpredictable variations in the transmitting medium. But while the path from sender to receiver is inherently constant with time, the cable possesses characteristics which provide some unusual problems of transmission. The measures which were adopted to insure an undistorted likeness of the original and to transmit the intelligence at a maximum rate within the limited frequency spectrum available through the cable, appear to be sufficiently unique to justify a description at some length.

This new system should not be confused with the "Bartlane" system of picture sending which was applied to cables for several years. In the Bartlane system the picture was analyzed into small unit squares, and a code character was set up corresponding to each unit. The characters were sent by means of the equipment ordinarily serving for telegraph transmission, and were decoded, usually automatically, at the receiving end. That system was inherently slow and made inefficient use of the available cable capacity as compared with the arrangement described herein.

Description of Cable Circuit

The transatlantic cable which is utilized for picture transmission, indicated in figure 1, extends from Penzance, England to a repeater point at Bay Roberts, Newfoundland and thence to Rockaway, New York. Conductors in lead covered cable complete the circuit from London, England through Bristol to Penzance, and from Rockaway to New York City. The submarine cable contains a central copper conductor which is provided with a continuous wrapping of permalloy tape for magnetic loading, and which in turn is covered with gutta percha for insulation.

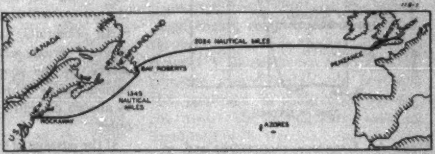
For picture transmission there are inserted repeaters of the electronic type, together with suitable signal shaping networks, at each of the above named points. The repeaters replace those in part mechanical which are in service when the cable is in telegraph operation.

In figure 2 is shown the electrical loss in each portion of the circuit, plotted against frequency.

Fundamental Transmission Requirements

The usual practice in picture transmission is to make use of a carrier current in the path from sending to receiving terminals. However, any carrier arrangement is wasteful of the available frequency spectrum, and in the case of submarine cable working it was especially necessary to minimize any waste. Therefore a carrier is not used in the cable in the system under discussion; instead the currents correspond directly with the shades of the original picture, varying from black, which produces maximum negative current in the cable, through gray to white which corresponds to maximum positive current.

Figure 1. Route of 1926 loaded submarine cable used for picture transmission



The transmission of a picture involves the sending and receiving of a large number of transient electrical currents. But every transient can be considered as the sum of a series of sinusoidal waves, and it is far more convenient to discuss the phenomena in terms of the ability of the system to transmit alternating current in a band of frequencies. In this case we are interested in the transmission from sender to receiver of all frequencies from near zero to about 110 cycles per second.

There is a definite upper limit of frequency which may be passed through a submarine cable. The cable, like radio, is subject to static interference, and because of the rapid increase in cable attenuation with frequency as shown in figure 2, the signal-to-noise ratio rapidly falls as the frequency is increased. In this cable the ratio becomes so low at about 110 cycles that currents at frequencies above this value tend to be lost in the interference. The receiving equipment is arranged to cut off shortly above this frequency in order to minimize as far as practicable the effects of outside interference.

It also is necessary to arrange the system so that the receiving equipment is insensitive to direct current or to alternating currents of very low frequency, otherwise it would be unworkable from time to time because of the earth potentials which affect ocean cables. Amounts of five volts or more occur al-

most daily, and at times when abnormal conditions occur on the surface of the sun, the voltages are much higher. Values as high as 500 volts have been recorded, although such amounts occur only at long intervals. Earth potentials may be considered to be very low frequency alternating voltages, the frequency ranging from perhaps one cycle per hour to two cycles per minute. The receiving picture system is made immune to such earth potentials, except at the very occasional periods when they are unusually severe, by the shaping networks at the various points, which are arranged largely to absorb currents at frequencies of this order.

If the passage of direct currents through the cable were desirable, their transmission would in fact have been difficult because of practical considerations in the design of the amplifiers, and because of the necessity of separating from the cables the high voltage batteries used as plate supply in power amplifiers, in order to prevent the possibility of damage to cable insulation. The condensers used for the purpose have the unavoidable effect of removing most current components of the lowest frequencies.

Any arrangement of telegraph or of picture transmission in which low frequencies and direct currents are not received would be inoperable unless some arrangement were provided to compensate for the missing components of the signal. In the present case this is accomplished

by an automatic adjustment of the received signal at the end of each scanning line in the picture. At that moment it is arranged to reduce to zero (corresponding to neutral gray in the picture) the current at the sending station. At the corresponding time there is cut into the circuit at the receiving station a set of equipment which measures the amount of current being received and automatically compensates for the current level if it departs from normal. Thus the next scanning line is started with the received level at its correct value.

In its passage through the system, the facsimile signal must be amplified sufficiently to overcome the cable attenuation at the highest frequency that is utilized, in addition to the unavoidable loss of energy in various elements of the equipment. The total available amplification from the sending photocell to the receiving lamp is approximately 420 decibels.

The shaping networks at various points perform the functions discussed in the past few paragraphs, and in addition they discriminate between different frequencies in a manner to compensate with some precision for their large difference in attenuation and phase shift in the cable. For example, a current at five cycles is reduced as much as 109 decibels, as compared with that at 100 cycles, by the shaping networks.

Theory of Signal Shaping

The combined effect of the shaping networks at all points determines the faithfulness of the final product and the efficiency of utilization of the available frequency spectrum. The problem is parallel to that encountered in telegraphy in endeavoring to transmit a maximum quantity of material within a given range of the frequency spectrum.

When a reversal from black to white occurs at the sending transmitter, the effect reaches the distant recorder in the form of an "arrival" voltage, rounded somewhat and possibly otherwise distorted from the shape of the current as sent. Each possible arrival curve corresponds to a definite "frequency characteristic" of the entire transmission system, which is the ratio of received to sent voltage plotted as a function of frequency, assuming that the transmitter has been replaced by a generator of sinusoidal currents. The choice of the frequency characteristic markedly influences the efficiency of the system.

The frequency characteristic comprises in general both an amplitude function and a phase function. An arrival curve is not received at the same instant that the reversal occurs at the transmitter; instead there is a slight delay, and that lag corresponds to a change in phase angle which is proportional to the frequency. Such a phase change is not of importance as affecting the efficiency. If such phase changes only are present the arrival curve is symmetrical. Basic theory* shows that any phase change other than in proportion to the frequency, which introduces components in the frequency characteristic in quadrature to the main component, causes the arrival curve to be nonsymmetrical. Such a phase response makes less effective use of the cable capacity.

Since the attenuation of a cable increases rapidly with frequency, and the higher frequencies are increasingly difficult to utilize, it might be expected that the preferred over-all frequency characteristic would be one which cuts off sharply at the upper end of the useful range. Investigation, however, shows that such a characteristic is associated with an arrival curve which oscillates to an objectionable extent both before and after the main reversal.

Plots of a number of symmetrical arrival curves, with their corresponding frequency characteristics, are illustrated in figure 3**. The characteristics have been so chosen (with equal area under each) that the maximum slope of each arrival curve is the same. The amount of resolution in the direction of scanning is approximately proportional to the mean frequency f_0. The effect of an abrupt cutoff of the characteristic is shown in curve *A*.

Entire freedom from oscillations in the arrival curve requires the use of a characteristic which with increasing frequency decreases quite gradually to zero, and which therefore is quite wasteful of cable capacity. Curve *D* is an example of such a characteristic. However, a desirable compromise between the efficiency of cable utilization and the appearance of the resulting picture is obtained by permitting a moderate overthrow and oscillation in the arrival curve, which is not objectionable and may be of advantage in accenting the lines of the image.

Frequency characteristics precisely like those just shown, and with the correct phase angles, could hardly be obtained through the use of equipment which it is practical to assemble, but fairly close approaches should be feasible providing that networks of sufficient complexity are used. The arrival curve and the amplitude of the frequency characteristic actually obtained over the cablephoto system are shown in figure 4. Phase angle changes, other than those proportional to frequency, are small, and the arrival curve therefore is nearly symmetrical.

Amplifying Equipment

A number of unique problems were encountered in providing the necessary amplification and signal shaping at various points along the route. The manner in which the signal level varies from point to point is indicated in figure 5.

The transmitter in London, figure 6, contains a light shutter ahead of the photocell which breaks the beam at the rate of 1,350 times per second. The output of the photocell in the form of a carrier is amplified, demodulated, again amplified and impressed upon the line in the form of a signal in which the various voltages from maximum negative to

maximum positive correspond to the shades from black to white. The wires which are available from London to Bristol and from Bristol to Penzance, set up as a metallic pair, are capable of handling frequencies somewhat above 120 cycles per second, but are not suitable for carrier working.

At Bristol the currents are passed through a type of repeater, figure 7, which in the interest of simplicity is arranged to amplify the higher frequency components only. The lower frequency components are by-passed around the amplifier.

At Penzance, figure 8, the currents are received from a metallic pair and after amplification are sent into a submarine cable which makes use of ground return. The metallic pair, while relatively free from interference between the wires, is subject to serious longitudinal interference. The problem of passing into a ground-return circuit the wide frequency range of the needed currents, while avoiding the longitudinal interference, is met by the use of a push-pull amplifier including a degenerating arrangement which renders it insensitive to longitudinal voltages, while amplifying the transverse signal voltages from the incoming pair.

The transformers and the condensers which were placed in circuit at certain points because of practical considerations, have the unavoidable effect of largely reducing some of the desirable frequency components in the signal, particularly those components below about 0.4 cycle per second. To correct for this loss there is inserted in the repeater at Bay Roberts, figure 9, and again in that at Rockaway, a network which through feed-back action serves to re-enforce the lowest frequencies, while having no influence upon the higher ones.

Shaping networks in addition to those just described are included at all points except at the terminals for the purpose of attenuating currents at the intermediate frequencies and controlling the phase angle to compensate for the varying attenuation of the cable at different frequencies. The complete transmission system is effective throughout the range from about 0.04 cycle per second to about 110 cycles, which is a ratio of highest to lowest frequency of about 2,750 times.

At Rockaway, figure 10, the currents after amplification are adjusted in level automatically in the manner previously described, at the end of each scanning line, in order to compensate for the absence of signal components below about 0.04 cycle per second. At that instant, because of the momentary reduction to zero of the output from London, the output of the Rockaway amplifier should also be zero. The relays in the automatic corrector are caused to vibrate rapidly at that time. If any difference in potential then exists across the amplifier, the grid of one of its tubes is adjusted quickly until the difference in potential is removed.

Times Wide World

Figure 11. Trafalgar Square. Photograph transmitted by cable from London to New York

Results

Typical photographs transmitted by cable are shown in figures 6 and 11. These were transmitted at the rate of 2.2 square inches per minute, with scanning at 60 lines per inch. The resolution in the direction of scanning is especially fine, and is sufficient to warrant an increase either in the number of scanning lines per inch or a decrease in the time of transmission of a given area of picture.

The Audio Noise of Transformers

W. C. SEALEY
MEMBER AIEE

Synopsis: When transformers are installed near inhabited districts, their noise must be limited to unobjectionable values. Consequently, means of predetermining noise levels from the design constants of the transformer and means of noise reduction become necessary. It has been determined that the audio noise of transformers originates in the change in dimensions (magnetostriction) produced in the core steel by the alternating magnetic flux. The vibration caused by the change in dimensions is transmitted to the air through the tank walls. The basic noise may be increased due to the resonant vibration of mechanical parts. Theoretical relations for the sound produced have been derived. These relations are checked by tests on commercial transformers.

Introduction

When power transformers are installed in locations remote from residences or other buildings used constantly by human beings, audio noise created by them is not a problem. However, as loads increase it becomes desirable to place larger transformers closer to inhabited districts. Large transformers can create sufficient noise as to make their presence in inhabited districts objectionable. In addition, the public is becoming more noise conscious and insistent on the elimination of objectionable noise of any kind.

Consequently, the calculation of the noise of a transformer from its design constants in order to predict the amount of the noise and a study of means of noise reduction becomes a practical necessity.

Origin of Noise of Transformers

Audio noise of transformers originates in the change in dimensions produced in the core steel when it is magnetized.

When iron is magnetized, its dimensions change due to the magnetization. Usually, the iron lengthens parallel to the flux lines and decreases in dimensions at right angles to the flux lines. The change in dimensions is extremely small. For example, a typical transformer punching 100 inches long will increase in length 0.0002 inches when the transformer is excited at full voltage.

Figure 1 shows percentage changes in length for typical transformer steel. Although small, the change in dimensions sets up sound waves in the manner common whenever rapid movement of a solid (in this case the steel) in contact with an elastic medium (air or oil) occurs. The intensity of the sound (in watts per square centimeter or similar units) is proportional to the square of the amplitude of vibration. When the magnetizing force is alternating as in a transformer, the sound waves issue continuously. Such is the source of noise in a transformer. Its origin is the vibration of the iron core caused by the change in dimensions commonly called magnetostriction.

Measurement of Noise*

A method of predetermining the noise of a transformer from its design is the first step in designing a quiet transformer. This requires, in turn, a satisfactory means of measuring noise and convenient units for expressing the amount of noise.

Noise can be expressed in a wide variety of ways. A fairly complete description would be a curve of watts per square centimeter versus time. It is obvious that such a curve does not lend itself to ready comparison and analysis. Recurrent sound may be expressed as the sum of its various harmonics each expressed in terms of its maximum amplitude. Such an expression is useful for sound analysis and is frequently used for this purpose in noise reduction. It may be obtained by recording the curve of intensity versus time and analyzing it into its harmonics, or by the more usual process of obtaining each harmonic separately by a harmonic analyzer.

However, such measurements do not result in the simplicity necessary for convenient general use. It is highly desirable to have a method of measurement of noise or sound intensity which can be expressed in terms of a single unit.

Such measurement is complicated by the fact that the human ear which is the final arbiter of noise has a different response for each different frequency of sound and in addition, the comparative response varies with the amplitude of the sound.

To take account of the variation in response of the ear to the various frequencies, the measurement must give weighted values to the intensities of the various frequencies. Standard curves for such weighting have been established. Using these curves as a base, the common method in use today for giving an over-all expression of the amount of noise is to express it in decibels. For example, a particular sound is said to have an intensity of 60 decibels.

The decibel is really the measure of the ratio of two amounts of power. Since the human ear responds to an extremely wide range of sound intensities, the decibel offers a convenient means of expression of sound intensity. The decibel is so expressed mathematically that the sound intensity increases ten times for each ten decibels increase in sound level. Mathematically the sound level in decibels =

$$10 \log_{10} \frac{I}{I_0}$$

where I_0 is the reference intensity for the scale in watts per square centimeter or similar units and I is the measured intensity in the same units. The reference level I_0 in common use at present is 10^{-16} watts per square centimeter which at a temperature of 20 degrees centigrade and a pressure of 760 millimeters of mercury corresponds to a pressure of 0.000204 dynes per square centimeter for plane or spherical free waves. Expressed in terms of the pressure, the sound level in decibels, $\text{db} = 20 \log \frac{P}{P_0}$ where P_0 is the reference sound pressure in dynes per square

Paper 41-10, recommended by the AIEE committee on electrical machinery and presented at the AIEE winter convention, Philadelphia, Pa., January 27–31, 1941. Manuscript submitted September 19, 1940; made available for preprinting December 19, 1940.

W. C. Sealey is electrical engineer in the transformer division of the Allis-Chalmers Manufacturing Company, Milwaukee, Wis.

* Further information can be found in the American Tentative Standards Z24.1, Z24.2, and Z24.3, and AIEE test code No. 520.

centimeter or similar units and P is the measured sound pressure in the same units. Suitable instruments have been developed for measuring the over-all sound level in decibels. Other instruments have been developed for analyzing a sound into its harmonics. At the present time these are not precision instruments in the same sense that the more common electrical measuring instruments are. However, they are sufficiently accurate to be extremely useful in sound level determination. One of the obstacles has been the difficulty of calibration so that readings with the same meter or other meters calibrated at different times will be the same.

Theoretical Variations of Sound With Weight

Based on these methods of expressing and measuring sound, theoretical relations for the noise of transformers are derived. It is general experience that the noise of a transformer varies with its size and that large transformers are usually more noisy than small transformers.

It is also well known that the noise of a given transformer increases as the applied voltage is increased. That is, the sound level of a transformer increases as the induction in the iron is increased.

According to the standards which have been established for measuring transformer noise, the sound intensity is measured one foot away from the major sound producing surface. Consequently the sound intensity measured is practically the sound intensity at the surface of the sound transmitting member.

The first relation derived is that between sound intensity and the weight of the transformer core. For transformers of similar proportions the core weight, W, is proportional to the length of the core L, raised to the third power.

Thus $W=K_1L^3$ where K_1 is a constant

When the transformers considered have the same induction in the iron core, the noise intensity, I, at the outside of the transformer is proportional to the square of the core length because of the general law that the noise intensity is proportional to the square of the amplitude of vibration and because the change in dimensions due to magnetostriction is proportional to the core length.

Thus $I=K_2L^2$ where K_2 is a constant

$$L=\frac{(W)^{1/3}}{(K_1)^{1/3}}$$

Substituting for L in: $I=K_2L^2$

$$I=K_3W^{2/3} \text{ where } K_3=\frac{(K_2)}{(K_1)^{2/3}}$$

or the noise intensity is proportional to the weight of the core raised to the two-thirds power when the induction in the iron is constant.

Since the sound level in decibels, db by definition, equals

$$10\log_{10}\frac{I}{I_0};\ \text{db}=10\log_{10}\frac{(K_3W^{2/3})}{(I_0)}$$

$$\text{db}=10\log_{10}\frac{(K_3)}{(I_0)}+\frac{20}{3}\log_{10}W$$

Where $K_4=10\log_{10}\frac{(K_3)}{(I_0)}=$ a constant when the reference intensity I_0 is constant

$$\text{db}=K_4+\frac{20}{3}\log_{10}W$$

or the noise level in decibels is equal to a constant plus 6.67 times $\log_{10}$ (weight).

From this relation, it is evident that changing the reference level does not change the slope of the curve, but merely the value of K_4.

Theoretical Variation of Sound With Induction

The second relation derived is that between sound intensity due to magnetostriction and the maximum induction in the iron. The curve of change in length due to magnetostriction (figure 1) is obtained from tests on small samples of iron tested one sheet at a time in a device for determining the change in length due to magnetization of the sheet.

If S is the per cent increase in length due to magnetostriction, and K is a suitable factor, the sound intensity, I, for a given transformer is equal to KS^2. If the relative proportions of the different harmonics of the sound to each other remain the same with variation in S, K will be a constant. This derivation applies to all cases where K may be assumed to be constant with permissible error.

If S_0 is the per cent increase in length for reference level of induction B_0, the sound intensity, I_0, at the reference level is equal to KS_0^2.

Since the sound level in decibels, db by definition equals $10\log_{10}\frac{I}{I_0}$;

$$\text{db}=10\times\log_{10}\frac{S^2}{S_0^2}=20\log_{10}\frac{S}{S_0}.$$

If in figure 1, the reference level is chosen as 12,000 gausses $S_0=0.000177$ per cent, and $\text{db}=20\log_{10}\frac{S}{0.000177}$.

By substituting values of S from figure 1, values for plotting curve A of figure 2 are obtained. Curve A of figure 2 shows the change in sound level in decibels, due to magnetostriction when the maximum induction in the iron changes.

Tested Variation of Sound With Induction

Curve B of figure 2 was obtained by testing with a sound level meter the sound intensity of complete commercial transformers. The values of decibels read on the meter were corrected to a reference level of 12,000 gausses by subtracting the db at 12,000 gausses from the values at other inductions. It will be noted that the agreement between curves A and B of figure 2 is very close. This is an indication of the correctness of the theoretical analysis and in addition an indication that the origin of the noise was the magnetostriction of the iron with at most a negligible quantity of noise from other sources.

If steel having different magnetostriction characteristics were used, curves similar to figure 2 for the different steel would be used for sound intensity determinations. For certain cases, accurate determination of curve A is involved but curve B can always be obtained directly from sound intensity measurements.

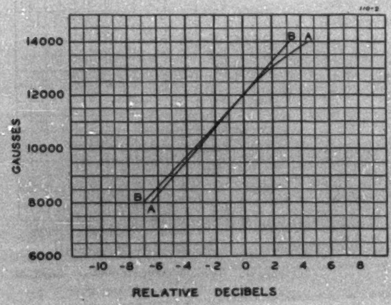

Figure 2. Variation of sound intensity with induction

Curve A—From magnetostriction tests on steel

Curve B—From sound level tests on complete transformers

Tested Variation of Sound Level With Core Weight

In order to check the correctness of the derived relation between noise in db and the core weight, a large number of sound level tests made on commercial transformer both in the shop and in the field were compared with calculated values.

Most of the tests were made at normal flux density for the transformers and in order to compare the values, they were reduced to a common flux density of 12,000 gausses. The values plotted in figure 3 are the sound intensity corrected to an induction of 12,000 gausses and the actual weight of the iron core in per cent of a common base.

The figure of 12,000 gausses to which the sound levels were corrected was chosen as being near the average induction of typical transformers. The correction was made by the use of figure 2. If W is the total weight of the core, W_1 is the weight of the part of the core considered, and its induction during the noise test was B_1, the value from figure 2 corresponding to B_1 was F_1, and the correction in db due to the part of the core considered was C_1, then $C_1=\left(\frac{(F_1W_1)}{W}\right)$. These corrections are obtained for the various parts of the core and added algebraically. In order to correct the sound reading obtained by test to the sound level corresponding to 12,000 gausses for plotting, the correction is subtracted algebraically from the test value. This method of making the corrections, is of course, an approximation but for the small variation in flux density which existed, the error introduced is negligible.

For example, a transformer has a tested noise level of 62 decibels. The weight of the core steel, W_1, is 2,000 pounds; B_1 its induction is 12,500 gausses; the weight, W_2, of the yoke steel is 3,000 pounds, its induction B_2 is 11,000 gausses. From figure 2, F_1 on curve A corresponding to 12,000 gausses is 1.0, F_2 corresponding to 11,000 gausses is −1.7.

$$C_1=\frac{F_1W_1}{W}=1.0\times\frac{2,000}{5,000}=0.4$$

$$C_2=\frac{F_2W_2}{W}=1.7\times\frac{3,000}{5,000}=-1.0$$

$$C_1+C_2=0.4-1.0=-0.6$$

The sound level of the transformer corrected to 12,000 gausses is $62-(-0.6)=$ 62.6 decibels.

This is the value which would be plotted in figure 3. Values obtained in this manner were plotted and the curves of figure 3 were obtained.

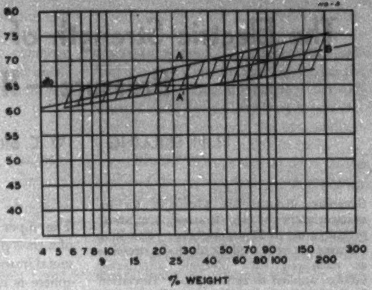

Figure 3. Variation of sound intensity with weight of core

Band *A*—*A'* indicates test values

Curve *B*—Theoretical curve

To obtain quantitative results from the data given for a particular transformer, the procedure is to obtain the decibel value for the transformer from figure 3 corresponding to the total weight. This is the decibels of the transformer at one foot provided all the iron were at an induction of 12,000 gausses. If the induction is at some other value, a correction for induction is made using figure 3.

EXAMPLE

A transformer with the following characteristics is assumed:

Core weight	30 per cent of the base weight
Yoke weight	50 per cent of the base weight
Total core weight	80 per cent of the base weight
Core induction	12,800 gausses
Yoke induction	11,500 gausses

The decibels corresponding to 80 per cent of the base weight on figure 3 is 69.3. From figure 2, curve A, the corrective decibels for the core =

$$\frac{30}{80}\times 1.6=0.6$$

The corrective decibels for the yoke = $50/80\times -0.9=-0.56$

The corrected decibels $=69.3+0.6-0.56=$ 69.34 decibels

The tested values as corrected for induction are shown by the shaded area between the lines A and A'. The straight line B is drawn through the approximate center of the band with a slope so that the sound intensity varies as the two-thirds power of the core weight. The slope of this line is the same as the slope of the shaded area within the limits of experimental error.

The weights in figure 3 are given as a percentage of an arbitrarily chosen base weight. The same curve can be used for other proportions or forms of construction after the correct base weight has been determined experimentally. The band width of the curves of figure 3 is due partly to variation in the magnetostriction of the steel itself. Some of the high points outside the band were probably due to resonance phenomena involving mechanical vibration of some part of the transformer.

Measurements on identical transformers extended over a large part of the band width. Physical proportions of the transformer also affect this sound level.

It was found that radiators had little effect on the sound level when the sound level was measured at one foot from the major sound producing surface in accordance with the latest standards. This is not wholly unexpected because the sound travels through oil and metal with little attenuation, and the sound wave transmitted is extremely complex.

In general, transformers with higher exciting currents, compared with identical transformers produced higher sound levels, but additional investigation is required before general conclusions on this subject can be offered with confidence.

Reduction of Noise

The reduction of the sound level of transformers is most effectively secured by reducing the induction in the iron. To produce quiet transformers, it is necessary that parts be so constructed that reasonant vibration is negligible. No successful method of reducing the transmission of sound to the air has been developed so far.

Generally most of the objectionable sound is borne by the air. In cases where sound is conducted through the supports, sound isolating devices may be used but the solution is difficult owing to the large low frequency components of the sound.

In the future, noise reduction through steel of lower magnetostriction may be expected.

The most variable quantity at present is the magnetostriction inherent in the

The Electric Strength of Air at High Pressure—II

H. H. SKILLING
MEMBER AIEE

W. C. BRENNER
ENROLLED STUDENT

Synopsis: Results are given of an investigation of the electric strength of air at pressures up to 21 atmospheres. Sparking voltages are presented for air under pressure as measured with 60-cycle alternating voltage applied to sphere gaps. Deviation from the linear pressure-voltage relation that exists at low pressures is discussed, and certain characteristics of sparking in compressed air are noted.

A STUDY of the electric strength of air under pressure was reported three years ago.[1] Because of increased interest in the subject this study has been extended, and parts of the work have been repeated with a higher degree of accuracy. Data thus obtained are of interest in the design of air-blast circuit-breakers and other types of compressed-air switches, gas-insulated transformers, power cables operating under pressure, gas-filled radio transmitting condensers, etc.

The present paper presents data relating to sparking between spherical electrodes in air, the air pressure ranging from 1 to 21 atmospheres (0 to 300 pounds per square inch gauge pressure). Results obtained with spherical electrodes may be applied with reasonable accuracy to any spark gap in which the electric field is substantially uniform. The results of this investigation are therefore applicable to sparking between the parallel plates of condensers, electrostatic shields of high-voltage apparatus, and other smooth surfaces. Breakdown between points, and at sharp edges, and between small wires, is discussed in the earlier paper.[1]

Apparatus

The spherical electrodes of the test gap, mounted in their supporting framework, are shown in figure 1. The spheres shown are approximately 20 millimeters or slightly less than one inch in diameter. The upper sphere is supported by means of a glass plate which insulates it from the metal framework. The stem of the upper sphere is electrically connected, through a spring, to the metal rod at the axis of the two glass cones near the top of the picture. These cones, clamped back-to-back, constitute the high-voltage bushing for the pressure tank in which testing is done. The axial rod through the cones serves as the high-voltage lead into the tank, and a connecting wire from the top of the rod to the high-voltage transformer may be seen in the picture. The heavy metal disk between the glass cones becomes the head of the pressure cylinder when the apparatus is assembled.

The lower sphere is adjustable vertically by means of a micrometer mechanism. The sphere may be raised or lowered without rotation. Springs are provided to prevent error due to backlash in the screw or bearings. To adjust the gap between spheres to its desired value the lower sphere is raised until it touches the upper sphere. Contact is indicated by a neon glow lamp that is connected in series with the gap while making this adjustment. The lower sphere is then lowered to its proper position as indicated by the micrometer calibration. Micrometer settings are read to 0.0001 inch.

The supporting framework for the gap is quite rigid. It is subjected to no stress other than its own weight, and the gap length is adjusted in the same position in which electrical testing is done. In particular, the supporting framework is so designed that changes of pressure of the gas do not change the length of the spark gap, as would occur if the spheres were supported from opposite ends of the tank. Temperature changes are not large, and since all major parts of the supporting framework are of the same material (steel) the gap length is not appreciably affected by expansion or contraction.

Dimensions and clearances are such that the gap is essentially a standard sphere spark gap as defined by AIEE standards.

For testing in gases other than air at atmospheric pressure the assembly shown in figure 1 is inserted in a pressure chamber as shown in figure 2. The cylinder, a 29-inch length of 10-inch steel oil well casing, is closed at top and bottom by heads of cast steel that are clamped together by 12 bolts as shown. Provision is made to admit gas to the test chamber through a pipe at the top, and two electric circuits other than the high-voltage circuit are led into the chamber by means of spark plugs. One of these circuits is used for a lamp to illuminate the interior of the chamber, and the second serves to operate a fan, to supply a source of ultraviolet radiation, and for other purposes as required. A shaft carried through a stuffing-box in the upper head allows adjustments of the spark-gap length to be made while the apparatus is assembled and under pressure. There are two small glass windows in the wall of the chamber.

High voltage is supplied to the test gap within the pressure chamber from either of two transformers, one rated 110 to 33,000 volts, 15 kva, and the other 220 to 300,000 volts, 300 kva. The latter transformer is equipped with a tertiary voltmeter winding, which is used for voltage measurement. When the 33 kv transformer is used, voltage is measured across the primary winding and the output voltage is obtained by means of the transformer turn ratio. A crest voltmeter is

---

steel. Consequently noise can be reduced by proper selection of the steel.

Conclusions

1. Transformer noise originates principally in the magnetostriction of the core iron.
2. Transformer noise can be calculated from the design constants using as a base magnetostriction tests of the core iron and the other relations given.
3. The most effective methods of reducing basic transformer noise are by reducing the induction in the iron or by reducing the magnetostriction of the iron.
4. The sound intensity produced by similar transformers with the same induction in the core, varies as the two-thirds power of the weight.
5. The sound intensity produced by a transformer with core iron having normal magnetostriction varies as the square of the magnetostriction. This relation can be used to compare the sound intensities produced at various inductions or to compare the sound levels of various core steels.

used for all measurements to eliminate error resulting from nonsinusoidal wave form. The over-all accuracy of voltage measurement was checked by comparison of measured values of sparking voltage between 20-millimeter spheres with AIEE standard values; the difference was less than 0.5 kv up to a reading of 40 kv, the highest voltage compared.

Resistance is used in the high-voltage connection to limit current in the test gap to one-half ampere. When sparking occurs the flow of current is interrupted at the end of the first quarter-cycle of 60-cycle current by a high-speed circuit breaker in the transformer primary circuit.

Voltage is continuously adjustable over the entire range of the transformers by means of a tap-changing transformer and an induction-type voltage regulator in the transformer primary circuit. During certain tests the transformer power is supplied from a synchronous sine-wave motor-generator set; in this case it is possible to adjust voltage by changing the generator field current as well as by means of the transformer and regulator.

Procedure

A generally uniform method of testing for the sparking voltage was followed. The spheres between which sparking was to take place were mounted in the micrometer head within the pressure chamber after having been cleaned and polished. Various methods of polishing were used, and no difference was found between polishing with rouge or metal polish, by hand or by motor-driven buffing wheel. In one case a motor-driven wire brush was used on steel spheres, and although it altered the appearance from a mirror surface to a matte surface it had no effect on the electrical behavior. The presence of an oil film on the spheres made no apparent difference in sparking voltage; however it is difficult to be sure that in any case the spheres were entirely free from oil because of the probability of oil being carried into the test chamber from either an air compressor or a storage cylinder.

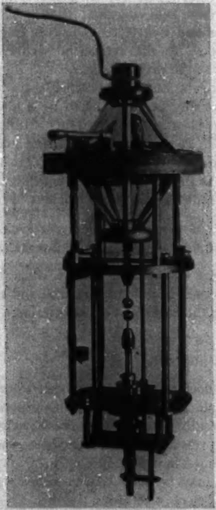

Figure 1. The sphere spark gap and supporting framework

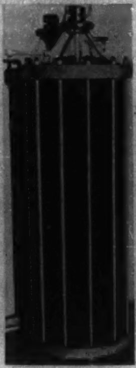

Figure 2. The test chamber containing air under pressure

When an air compressor was used the air was cooled and filtered before being admitted to the test chamber. Despite the filtering, particles of oil of extremely small size were carried into the test chamber. Although the presence of the resulting haze of oil particles within the chamber had no noticeable effect on the sparking voltage, its presence resulted in a black oily deposit on the sphere surfaces after continued sparking. This was avoided by compressing the air several hours before it was used, thereby allowing the oil particles to settle out; when this procedure was followed the compressed air was perfectly clear and free from haze.

Before measuring sparking voltage the gap was adjusted to the desired length. A zero setting of the micrometer was obtained by means of a neon glow lamp, as described above. The micrometer setting was read when the lamp lighted as the spheres were being brought together and when it went out as they were separated. The difference between the two readings was normally less than 0.0001 inch.

Sixty-cycle voltage was applied to the gap, and the voltage was raised gradually until a spark occurred. The time required to raise voltage to sparking value varied from a few seconds to about half a minute, and sometimes was extended over several minutes. In some cases the speed of application of voltage was an important factor, as will be discussed.

At each particular spacing and pressure a number of readings of sparking voltage were measured and recorded. The number of readings depended upon circumstances, and particularly upon the uniformity of the measurements. If the first eight or ten sparks were at substantially the same voltage (within two or three per cent) they were considered satisfactory, but if there were radical variations the test was continued until 20, or 40, or as many as 100 sparking voltages were recorded. Either the pressure or the spacing was then changed and another series of readings was made.

Several series of tests were made with a quartz-tube mercury-arc lamp so located within the pressure chamber that its light fell on the spheres and passed through the gap between the spheres. It is impossible to say that its presence made any significant difference in the results, either in the value of voltage or in consistency of results. Use of the lamp was not continued.

Interpretation of Data

An *average* of the several voltage readings at any given spacing and pressure is not adequate to represent the results. There is apparent in much of the data a distinct trend:[4] the first sparking voltages are low and succeeding ones are higher in such a way that they appear to approach a limit. After four or five sparking voltages have been measured in rapid succession (less than a minute apart) the value of sparking voltage becomes stabilized. There is frequently a gradual rise of ten per cent or more in sparking voltage from the first spark to the fourth or fifth, while random variations of sparking voltage thereafter are not likely to vary more than one or two per cent from the trend value. If the series of sparking measurements is interrupted for five or ten minutes, however,

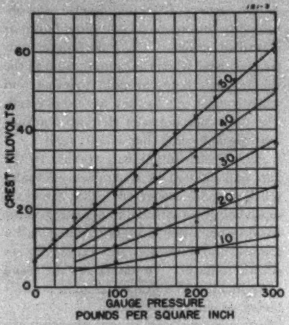

Figure 3. Sparking in air between brass spheres. Spark gap length as noted on curves in thousandths of an inch

and is then recommenced, it is probable that the first few sparks after interruption will occur at slightly reduced voltage and the stabilized value will have to be re-established. Occasionally, also, there is a break from the stabilized sparking voltage for no apparent reason; a spark will occur several per cent below the trend voltage, and successive sparks will be consecutively higher until the stabilized value is again reached.

An upward trend at the beginning of a series of sparks was found in most voltage measurements in which the voltage was greater than about 30 kv; that is, in case of either high pressure or relatively long spark gap. There was no such trend observed at atmospheric pressure, or in most measurements below about 20 kv. Under no circumstances was there any appearance of a downward trend; the voltage readings were either quite consistent or else the erratic readings were below the stabilized value. The amount of variation between the stabilized value of voltage and the lowest sparking voltages was of the order of magnitude of ten per cent.

The stabilized value of voltage is reproducible from time to time; an average voltage value, on the other hand, cannot readily be repeated and is not particularly significant because it depends on the number of measurements at a given setting of the gap and on the history of sparking of the gap. Therefore the stabilized value of voltage has been accepted as the best value to use in representing test results in this paper. It must be recognized that a reasonable engineering value of sparking voltage is about ten per cent below the values here given because of the likelihood of occasional sparks at voltages below the stabilized value.

To a slight extent the sparking voltage at high pressure was dependent upon time of application of voltage. The stable trend value was found by raising voltage at such a rate that sparks were produced at the rate of one or two per minute. If, after the stable condition had been established, voltage two or three per cent lower than the stable sparking value was applied continuously, sparking would usually occur after some time. The time that elapsed before sparking in such a case might be from a few seconds to ten minutes. If the applied voltage was as much as five per cent below the trend value, sparking might be delayed 30 minutes. Applied voltages ten per cent or more below the trend value did not produce sparking regardless of time. To insure steady voltage supply for these tests, power was taken from a motor-generator set.

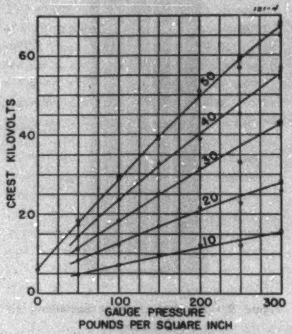

Figure 4. Sparking in air between steel spheres. Spark gap length as noted on curves in thousandths of an inch

It is believed that the rising trend of sparking voltage and the time lag of sparking are associated phenomena, for they appeared under the same conditions.

Results

Results are shown in figures 3 and 4. Each indicated point represents a stabilized value determined from a series of individual voltage readings. About 2,000 individual readings of sparking voltage are represented by these sets of curves.

The data of figure 4 may be presented in another form which is more compact, although less convenient for reference. This is done by plotting the sparking voltage as a function of the product of the independent variables, pressure, and spacing between electrodes. This product may be designated *PS*; the pressure *P* is most conveniently measured in atmospheres, and the spacing between electrodes, *S*, may be in inches.

According to the law for sparking commonly known as Paschen's law[3,4,5], voltage at breakdown should be a function of the product *PS*. Numerically, Paschen's law may be expressed[3] in the above units as

$$V = 75.4PS + 1.7 \text{ kilovolts} \qquad (1)$$

If Paschen's law could be extrapolated from the low pressure range, below one atmosphere, for which it was determined, to cover the many-times greater range up to 21 atmospheres, the experimental points from figure 3 should all lie on a single straight line when plotted against the product *PS*. That this is approximately true may be seen in figure 5, in which all experimental points could be represented by a single straight line with an error not exceeding ten per cent. There is, however, a consistent deviation that corresponds to the drooping curvature of the lines of figure 3, and sparking voltages at high pressure are lower than sparking voltages for the same value of *PS* at low pressure.

In earlier papers[1] it has been suggested that this systematic deviation might result from field emission; that is, it might be caused by electrons drawn from the cathode by the extremely high electric field at the cathode surface. If this is so the deviation from Paschen's law could reasonably be expected to be a function of the electric field strength.[3] Inspection of figure 5 suggests the following modified expression for sparking voltage, in which V/S is the electric field strength between electrodes, and a is a coefficient to be determined from the data:

$$V = 76.0PS(1 - aV/S) + 1.7 \text{ kilovolts} \qquad (2)$$

Solving for sparking voltage, discarding a term of negligible importance, and evaluating the coefficient a, one obtains:

$$V = \frac{76.0PS}{1 + 0.009P} + 1.7 \text{ kilovolts} \qquad (3)$$

The coefficient has here been evaluated to make equation 3 agree with experimental results obtained with *brass* electrodes. The pressure *P* is in atmospheres and the spacing *S* in inches.

It may be seen that results obtained with steel electrodes (figure 4) differ slightly from results with brass electrodes (figure 3). Sparking voltages at pressures less than about 50 pounds per square

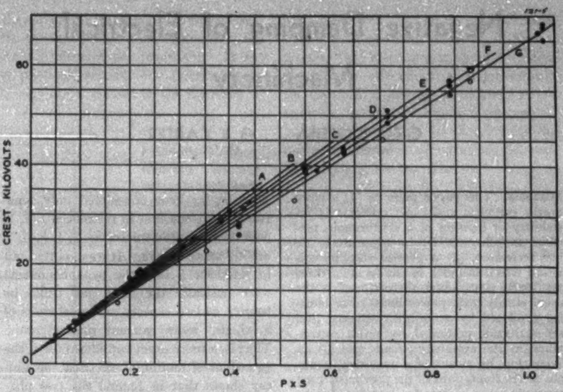

Figure 5. Sparking in air between brass spheres

P, absolute air pressure in atmospheres; *S*, spark gap length in inches. Points shown are experimental, lines are computed from equation 3

Line *A* and points marked ◐ are for 0 pounds per square inch pressure

Line *B* and points marked ⊕ are for 50 pounds per square inch pressure

Line *C* and points marked ⊙ are for 100 pounds per square inch pressure

Line *D* and points marked ⊖ are for 150 pounds per square inch pressure

Line *E* and points marked ● are for 200 pounds per square inch pressure

Line *F* and points marked ○ are for 250 pounds per square inch pressure

Line *G* and points marked ⊗ are for 300 pounds per square inch pressure

inch are the same for steel and brass, and both agree with Paschen's law. At higher pressures the deviation from Paschen's law is greater for steel than for brass. If the deviation is assumed to be a result of field emission, it is not surprising that it should be different with different electrode materials. A difference between sparking voltage with iron and copper electrodes was noted in an earlier paper by one of the authors;[1] although it was not at that time known to be significant, it now appears comparable to the difference between steel and brass shown by figures 3 and 4.

Values of sparking voltage were measured between aluminum spheres, also. Results using aluminum electrodes in air were inclined to be erratic, some sparking voltages being as high as the values obtained with brass spheres while others were lower than results with steel. Repeated sparking between aluminum spheres in air tended to reduce the sparking voltage, the inference being that a chemical change of the electrode surfaces was taking place. (Aluminum electrodes give consistent results, comparable with brass electrodes, when used in nitrogen.)

To describe results obtained with *steel* electrodes an expression of the form of equation 3 may be used:

$$V = \frac{76.0PS}{1+0.019P} + 1.7 \text{ kilovolts} \qquad (4)$$

The coefficient in the denominator is here adjusted to give as good agreement as possible with the data of figure 4; agreement is within about ten per cent.

Although this expression for steel electrodes was derived to fit the experimental results obtained by the authors, it gives excellent agreement with sparking voltages measured by A. H. Howell.[5] Howell's electrodes were "turned from ordinary cold rolled steel." His results, although obtained with direct current from a Van de Graaff generator, appear to extend the range of equation 4 to pressures as high as 600 pounds per square inch and values of the product *PS* as great as ten.

Equation 4 also gives reasonably good agreement with results obtained by R. C. Buehl[6] with 60-cycle alternating voltage in nitrogen up to pressures of 140 atmospheres (2,060 pounds per square inch) and *PS* of seven. Agreement is within ten per cent for most of Buehl's data.

It is, furthermore, evident that Paschen's law may be considered a special case of equations 3 or 4 that applies with good accuracy when the air pressure is below about five atmospheres. Since Paschen's law has been experimentally substantiated for values of *PS* as low as 0.05 for pressures below atmospheric, it follows that equations 3 and 4 are accurate in that region also.

These considerations indicate the useful range of application of equations 3 and 4.

ASSOCIATE AIEE

Synopsis: This paper presents (1) a more nearly complete and exact criterion of instability or hunting of a synchronous machine as influenced by its armature or tie line resistance, (2) a general stability criterion which includes in one formula three previously separately treated cases: the usual steady state power limit, rotor hunting produced by armature resistance, and self-excitation produced by series capacitance in the armature circuit, and (3) an indication, by means of a numerical example, of the limitations of the previously used approximate criterion for hunting due to armature resistance.

IN PREVIOUS treatments, hunting, self-excitation, and loss of synchronism have been considered only separately, neglecting their mutual interactions. The present paper, on the other hand, considers their mutual effects and thus provides a general analysis by reference to which the limitations and proper fields of application of the approximate formulas may be found. Application of the complete criterion given is however rather laborious, and it is not suggested for general use in place of the approximate forms.

Introduction

When synchronous machines are tied together through impedances having rather high resistance components, and when there is insufficient rotor damping, the machines tend to hunt. Also, when a machine is connected to a capacitance load or to a system through a series capacitor there is exhibited under certain conditions a tendency to self-excite. Both of these phenomena have been treated extensively in electrical engineering literature, and the conditions under which one or the other form of operation is to be expected are reasonably well known. However, the two phenomena have so far been considered only separately, e.g., the first in references 1, 2, 3, and the second in references 3, 4, 5, 6, 7, among many others. It was pointed out in reference 3 that the two phenomena were basically the same and could be treated as two aspects or special cases of a single, more general characteristic. That is, a more exact consideration of the equations of motion of electrical machinery shows that in general the two phenomena are mutually dependent and in fact inseparable, and that it is only because of the relatively large differences in the orders of magnitudes of the principal controlling features of each that they can be approximately separated. Since all previous treatments have considered them separately and have consequently neglected their mutual interactions, it was felt that an investigation should be made to find out just what these interactions might be. The results of such an investigation, comprising a quantitative study of the complete equations of motion of a simple electromechanical system, are presented in this paper.

Preliminary Considerations

Before proceeding to the combining of self-excitation and hunting into a single form (here called negative damping), the simpler case of a system which can show only hunting was first studied, since it has been found that the behavior of this system according to the equations used here is somewhat different from that according to the approximate criteria previously given.[1]

A single synchronous machine with only one rotor winding, connected to an infinite bus, may become unstable at small generator angles or at any motor angle if the armature resistance is too high, and at large generator angles if the armature resistance is too low. Both concepts are well known, but the latter may be amplified by pointing out that at large generator angles and high resistances the system, although stable, has only a negligible synchronizing torque and load capacity.

Figures 1 and 2 show the results of stability calculations made for this case. The regions of stable operation were determined by the application of Routh's[11] stability criterion to equation 6 of the appendix. Figure 1 is for comparatively low values of armature resistance; in this figure, the solid line represents the stability limit for unit field excitation, the dashed line that for one and a half times unit excitation. For comparison, the hunting criterion $r \leqq x_q \tan \delta$, of reference 1, is also shown, as a dot-and-dash line for generator angles.

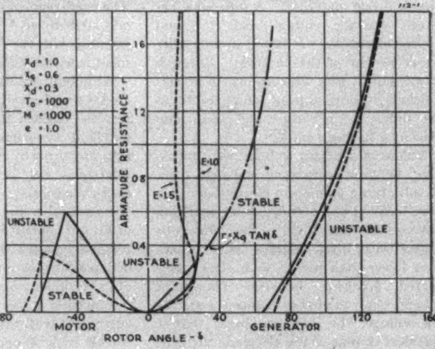

Figure 1. Synchronous machine connected to infinite bus—stability limits—effect of armature resistance r and field excitation E

It is seen that the approximate criterion is optimistic for small angles and pessimistic for larger generator angles; for the larger motor angles (from about 30 degrees to the steady state boundary) the approximate criterion $r = x_q \tan \delta$ agrees fairly closely with the more nearly exact criterion used here. At light loads figure 1 indicates that $r \leqq x_d' \tan \delta$ would be a

Paper 41-12, recommended by the AIEE committees on power transmission and distribution, and electrical machinery, and presented at the AIEE winter convention, Philadelphia, Pa., January 27–31, 1941. Manuscript submitted October 11, 1940; made available for preprinting November 26, 1940.

C. Concordia is engineer, central station department, General Electric Company, Schenectady, N. Y.; G. K. Carter is in the engineering general department of the same company.

[1] For all numbered references, see list at end of paper.

better criterion of stability than $r \leqq x_q \tan \delta$, at least for the value of field time constant $T_0=1{,}000$ studied. The more nearly exact criterion shows no instability due to high armature resistance for generator angles of more than about 30 degrees. This is not in conflict with experience, since those cases of hunting which have actually been encountered have usually occurred only at light load. Another check is obtained by noting that the amount of armature resistance required to produce negative damping at light loads decreases as the field excitation is increased, which is consistent with the observation that the severity of hunting is usually increased by increased excitation. The outer boundaries of figure 1 are found to check the steady state stability limits determined by the usual steady state power-angle relations.[12]

Figure 2 is of only theoretical interest, as the resistances involved are so high that the machine armature is practically open circuited.

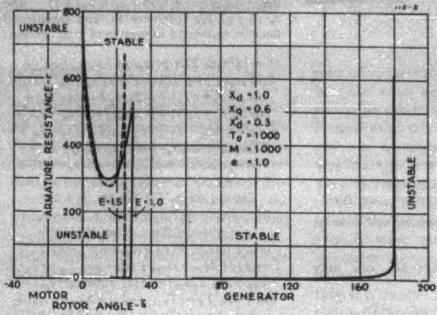

Figure 2. Synchronous machine connected to infinite bus—stability limits—effect of armature resistance r and field excitation E at high values of r

Negative Damping With Series Capacitors

Figure 3 shows some of the results of stability calculations made for the general case of a synchronous machine connected to a bus through a series capacitor. Equation 4 of the appendix gives the equation for this case. In a general way the correspondence of this stability boundary to those which would be obtained by the previous approximate methods is that first, the left hand rising portion of the curve corresponds roughly to the lower portion of the curve for $M=\infty$ of figure 1, reference 5, and second, the right hand decreasing portion corresponds to the boundary which would be found by application of the approximate criterion for hunting if the capacitive reactance x_c is subtracted from the quadrature axis reactance x_q to form an effective net reactance. As in the previous section, the criterion $r \leqq (x_d'-x_c) \tan \delta$ (shown in the figure by a dashed line) forms a better, in fact a rather good, criterion.

Figure 3 indicates that instability may occur if the resistance is too small and if the resistance is too large. An amortisseur on the machine rotor will increase the maximum allowable armature resistance so much as practically to remove any upper (right hand in figure 3) boundary. On the other hand the allowable minimum resistance will also be increased, as indicated by figure 4. Figure 4 has been calculated by the equations of reference 5, and may be compared to figure 1, reference 5, to show the effect of the amortisseur. The fact that an amortisseur does not tend to suppress the negative damping introduced by series capacitance need not be alarming however, as figure 5 shows that resistance in shunt with the capacitor is still effective in preventing the instability, just as was found in reference 3, figure 18. Figure 5 was calculated from equation 1d of reference 3, using an extension of equations 2d and 3d to include the amortisseur.[10]

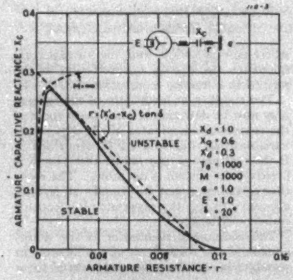

Figure 3. Synchronous machine connected to infinite bus through armature series capacitance—stability limits at rotor angle $\delta=20$ degrees

Conclusions

1. A more complete and exact criterion of instability of a synchronous machine as influenced by armature resistance has been derived by application of Routh's test to the system performance equations.

2. A general criterion of instability has been derived which includes three previously separately treated cases: the normal steady state power limit, rotor hunting produced by armature resistance, and self-excitation produced by series capacitance in the armature circuit.

3. The limitations of the previously used approximate criterion for hunting due to armature resistance have been determined.

4. The effect on the stability limit of series capacitance in the armature circuit has been studied by the more complete criterion and shown to agree fairly well with the approximate criteria for appropriate limiting conditions.

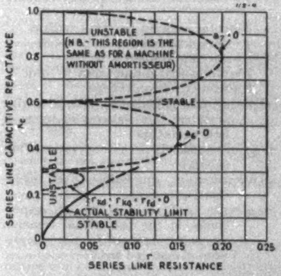

Figure 4. Negative damping of synchronous machines with series capacitors—effect of amortisseur. Series resistance required for stable operation

$x_d=1.0$ $x_d'=0.3$ $x_d''=0.218$
$r_{kd}=0.02$ $T_0=1{,}000$, $\omega=1.0$, $\alpha=0$
$x_q=0.6$ $x_q''=0.311$ $r_{kq}=0.04$
($a_7=0$, $a_6=0$, etc., are approximate criteria)

Appendix

Nomenclature

r = armature circuit resistance
δ = angle between rotor axis and axis of stator voltage

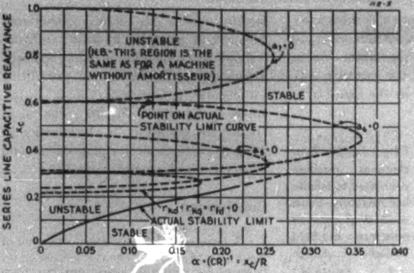

Figure 5. Negative damping of synchronous machines with series capacitors—effect of amortisseur. Shunt resistance required for stable operation

$x_d=1.0$ $x_d'=0.3$ $x_d''=0.218$
$r_{kd}=0.02$ $T_0=1{,}000,\ \omega=1.0,\ r=0$
$x_q=0.6$ $x_q''=0.311$ $r_{kq}=0.04$
($a_7=0$, $a_6=0$, etc., are approximate criteria)

x_d = direct axis synchronous reactance
x_q = quadrature axis synchronous reactance
x_d' = direct axis transient reactance
x_d'' = direct axis subtransient reactance
x_q'' = quadrature axis subtransient reactance
T_0 = field open circuit time constant
x_c = armature circuit capacitive reactance
R = resistance in parallel with x_c
$\alpha=x_c/R$
M = rotor inertia factor in radians
e = stator voltage
i = stator current
ψ = stator flux linkages
(subscripts d and q indicate direct and quadrature axis components, respectively)
θ = rotor angle in electrical radians
p = time derivative operator $=d/dt$
$(p\theta)=\omega$ = rotor angular velocity
T = mechanical torque input to rotor
E = field excitation voltage
$G(p)$ = mutual impedance operator giving armature flux linkages in terms of field excitation
$x_d(p)$ = armature direct axis operational impedance
$x_q(p)$ = armature quadrature axis operational impedance
a_7, a_6 = the coefficients of p^0, p^1, respectively, in the operational common denominators used in the calculations of figures 4 and 5

Analysis

In this appendix the equations of a synchronous or induction machine with a capacitor and resistor in parallel in the armature circuit are extended to include the effect of rotor inertia during small changes (e.g., oscillations) of rotor speed. The fundamental equations for this case have been derived in references 5, 8, and 9, and are:

$$\left.\begin{aligned}
&(p+\alpha)[e_d-p\psi_d+ri_d+\psi_q(p\theta)]+x_ci_d-\\
&\qquad(p\theta)[e_q-p\psi_q+ri_q-\psi_d(p\theta)]=0\\
&(p+\alpha)[e_q-p\psi_q+ri_q-\psi_d(p\theta)]+x_ci_q+\\
&\qquad(p\theta)[e_d-p\psi_d+ri_d+\psi_q(p\theta)]=0\\
&T=\psi_di_q-\psi_qi_d+Mp^2\theta
\end{aligned}\right\}\quad(1)$$

where

$$e_d=e\sin\delta\qquad \psi_d=G(p)E-x_d(p)i_d$$
$$e_q=e\cos\delta\qquad \psi_q=-x_q(p)i_q$$

and the other symbols are as defined in reference 8 and in the nomenclature. From equations 1, by taking small changes in e, E, i_d, i_q, and $\delta(\Delta\theta=\Delta\delta)$, one may obtain:

$$\left.\begin{aligned}
&[(p+\alpha)(px_d(p)+r)+x_c-\omega_0^2x_d(p)]\times\\
&\Delta i_d-[(p+\alpha)\omega_0x_q(p)+\omega_0(px_q(p)+r)]\times\\
&\Delta i_q+\{[(p+\alpha)\psi_{q0}+2\omega_0\psi_{d0}-e_{q0}-ri_{q0}]\times\\
&p+(p+\alpha)e_{q0}+\omega_0e_{d0}\}\,\Delta\delta=[-(p+\alpha)\times\\
&\sin\delta_0+\omega_0\cos\delta_0]\,\Delta e+[(p+\alpha)p-\omega_0^2]\times\\
&\qquad\qquad G(p)\,\Delta E\\
&[(p+\alpha)\omega_0x_d(p)+\omega_0(px_d(p)+r)]\,\Delta i_d+\\
&[(p+\alpha)(px_q(p)+r)+x_c-\omega_0^2x_q(p)]\,\Delta i_q+\\
&\{[-(p+\alpha)\psi_{d0}+2\omega_0\psi_{q0}+e_{d0}+ri_{d0}]p-\\
&(p+\alpha)e_{d0}+\omega_0e_{q0}\}\,\Delta\delta=[-(p+\alpha)\cos\delta_0-\\
&\omega_0\sin\delta_0]\,\Delta e+(2p+\alpha)\omega_0G(p)\,\Delta E\\
&-[\psi_{q0}+i_{q0}x_d(p)]\,\Delta i_d+[\psi_{d0}+i_{d0}x_q(p)]\times\\
&\qquad\Delta i_q+Mp^2\,\Delta\delta=\Delta T-i_{q0}G(p)\,\Delta E
\end{aligned}\right\}\quad(2)$$

where $\omega_0=(p\theta)_0=1.0$, and the steady state quantities ψ_{d0}, ψ_{q0}, i_{d0}, i_{q0} are found as described in reference 5, equations 32, 33, 34.

The stability or instability of the system may now be determined from the p roots of the common denominator of the dependent variables Δi_d, Δi_q, and $\Delta\delta$ in equations 2. If the real part of any one of these roots is positive, the system is unstable. The roots themselves need not be found; it is only necessary to test the expression by Routh's stability criterion.[11]

The common denominator is the determinant of the coefficients of the dependent variables in equations (2), and is equal to:

$$\begin{aligned}
D=\{&[(p+\alpha)(px_d(p)+r)+x_c-\omega_0^2x_d(p)]\times\\
&[(p+\alpha)(px_q(p)+r)+x_c-\omega_0^2x_q(p)]+\\
&[(p+\alpha)\omega_0x_d(p)+\omega_0(px_d(p)+r)]\times\\
&[(p+\alpha)\omega_0x_q(p)+\omega_0(px_q(p)+r)]\}\,Mp^2+\\
&[\![\{[(p+\alpha)\psi_{q0}+2\omega_0\psi_{d0}-e_{q0}-ri_{q0}]p+\\
&(p+\alpha)e_{q0}+\omega_0e_{d0}\}[(p+\alpha)\omega_0x_d(p)+\\
&\omega_0(px_d(p)+r)]-\{[-(p+\alpha)\psi_{d0}+\\
&2\omega_0\psi_{q0}+e_{d0}+ri_{d0}]p-(p+\alpha)e_{d0}+\\
&\omega_0e_{q0}\}[(p+\alpha)(px_d(p)+r)+\\
&x_c-\omega_0^2x_d(p)]]\!][\psi_{d0}+i_{d0}x_q(p)]+\\
&[\![[(p+\alpha)\omega_0x_q(p)+\omega_0(px_q(p)+r)]\times\\
&\{[-(p+\alpha)\psi_{d0}+2\omega_0\psi_{q0}+e_{d0}+ri_{d0}]p-\\
&(p+\alpha)e_{d0}+\omega_0e_{q0}\}+[(p+\alpha)(px_q(p)+r)+\\
&x_c-\omega_0^2x_q(p)]\{[(p+\alpha)\psi_{q0}+2\omega_0\psi_{d0}-\\
&e_{q0}-ri_{q0}]p+(p+\alpha)e_{q0}+\omega_0e_{d0}\}]\!]\times\\
&[\psi_{q0}+i_{q0}x_d(p)]
\end{aligned}\quad(3)$$

With $M=\infty$, equation 3 reduces to that for the previously treated case of constant rotor speed (reference 3, appendix D). Also if the machine is initially unexcited, so that $\psi_0=i_0=0$, the regions of stable operation are the same as before. In the general case, however, the performance will be affected by the operating angle, machine inertia, and excitations.

For a machine with only one rotor winding, $x_d(p)=(x_d'T_0p+x_d)/(T_0p+1)$ and $x_q(p)=x_q$ (see reference 8), and equation 3 may be expanded in powers of p to become:

$$\begin{aligned}
D'=\{&p^5x_qx_d'T_0+p^4[x_qx_d+rT_0(x_q+x_d')+\\
&2\alpha T_0x_qx_d']+p^3[(2x_qx_d'+x_c(x_q+x_d'))T_0+\\
&r(x_d+x_q+rT_0)+\alpha(2x_dx_q+\alpha x_qx_d'T_0)+\\
&2\alpha rT_0(x_q+x_d')]+p^2[2x_dx_q+x_c(x_d+x_q)+\\
&r(T_0(2x_c+x_q+x_d')+r)+\alpha(T_0x_c(x_q+x_d')+\\
&2T_0x_qx_d'+\alpha x_dx_q)+\alpha r(2x_d+2x_q+2T_0r+\\
&T_0\alpha(x_q+x_d'))]+p[T_0(x_c-x_q)(x_c-x_d')+\\
&r(x_d+x_q+2x_c+rT_0)+\alpha(x_c(x_d+x_q)+\\
&2x_dx_q+\alpha x_qx_d'T_0)+\alpha r(2x_cT_0+2r+\\
&\alpha(x_d+x_q)+\alpha rT_0)]+[(x_d-x_c)(x_q-x_c)+\\
&r^2+\alpha^2x_dx_q+2\alpha rx_c+(\alpha r)^2]\}\,Mp^2+\\
&(\psi_{d0}+i_{d0}x_q)\{p^5(x_d'T_0\psi_{d0})+p^4[-x_d'T_0\times\\
&(-\alpha\psi_{d0}+2\psi_{q0}+ri_{d0})+(x_d+\alpha x_d'T_0+rT_0)\times\\
&\psi_{d0}+2x_d'T_0\psi_{q0}]+p^3[x_d'T_0(\alpha e_{d0}-e_{q0})-\\
&(x_d+\alpha x_d'T_0+rT_0)(-\alpha\psi_{d0}+2\psi_{q0}+ri_{d0})+\\
&(\alpha x_d+r+\alpha rT_0-x_d'T_0+x_cT_0)\psi_{d0}+\\
&2x_d'T_0(\alpha\psi_{q0}+2\psi_{d0}-ri_{q0})+(2x_d+rT_0+\\
&\alpha x_d'T_0)\psi_{q0}]+p^2[(x_d+\alpha x_d'T_0+rT_0)(\alpha e_{d0}-\\
&e_{q0})+(2x_d+rT_0+\alpha x_d'T_0)(\alpha\psi_{q0}+2\psi_{d0}-\\
&ri_{q0})-(\alpha x_d+r+\alpha rT_0-x_d'T_0+x_cT_0)\times\\
&(-\alpha\psi_{d0}+2\psi_{q0}+ri_{d0})+(r+\alpha x_d)\psi_{q0}+(x_c-\\
&x_d+\alpha r)\psi_{d0}+2x_d'T_0(\alpha e_{q0}+e_{d0})]+p[(\alpha x_d+\\
&r+\alpha rT_0-x_d'T_0+x_cT_0)(\alpha e_{d0}-e_{q0})+(2x_d+\\
&rT_0+\alpha x_d'T_0)(\alpha e_{q0}+e_{d0})-(x_c-x_d+\alpha r)\times\\
&(-\alpha\psi_{d0}+2\psi_{q0}+ri_{d0})+(r+\alpha x_d)\times\\
&(\alpha\psi_{q0}+2\psi_{d0}-ri_{q0})]+[(x_c-x_d+\alpha r)\times\\
&(\alpha e_{d0}-e_{q0})+(r+\alpha x_d)(\alpha e_{q0}+e_{d0})]\}+\\
&[(\psi_{q0}T_0+i_{q0}x_d'T_0)p+(\psi_{q0}+i_{q0}x_d)]\times\\
&\{p^4(\psi_{q0}x_q)+p^3[\psi_{q0}(\alpha x_q+r)+(\alpha\psi_{q0}+\\
&2\psi_{d0}-ri_{q0})x_q-\psi_{d0}2x_q]+p^2[\psi_{q0}(r\alpha+\\
&x_c-x_q)+(\alpha\psi_{q0}+2\psi_{d0}-ri_{q0})(\alpha x_q+r)+\\
&(\alpha e_{q0}+e_{d0})x_q-\psi_{d0}(\alpha x_q+r)+(-\alpha\psi_{d0}+\\
&2\psi_{q0}+ri_{d0})2x_q]+p[(\alpha\psi_{q0}+2\psi_{d0}-ri_{q0})\times\\
&(r\alpha+x_c-x_q)+(\alpha e_{q0}+e_{d0})(\alpha x_q+r)+\\
&(-\alpha\psi_{d0}+2\psi_{q0}+ri_{d0})(\alpha x_q+r)-\\
&(\alpha e_{d0}-e_{q0})2x_q]+[(\alpha e_{q0}+e_{d0})(r\alpha+x_c-x_q)-\\
&(\alpha e_{d0}-e_{q0})(\alpha x_q+r)]\}
\end{aligned}\quad(4)$$

Note that the coefficient of Mp^2 in this equation is the Δ' of equation 4d, appendix D, of reference 3.

Equation 4 may be used to find the effect of rotor inertia on negative damping in the region of series capacitor applications where the machine is connected to an excited bus through a capacitor. For a capacitance load, as for transmission line capacitance, e_{d0} and e_{q0} should be taken as zero, in which case the effect of rotor oscillations on the borderline of stability is believed to be negligible, as there are no synchronizing torques.

For the special case of no armature circuit capacitance ($x_c=0$ or $\alpha=\infty$), the performance equations 2 become

$$\left.\begin{aligned}
&-(px_d(p)+r)\,\Delta i_d+\omega_0x_q(p)\,\Delta i_q-\\
&\qquad(\psi_{q0}p+e_{q0})\,\Delta\delta=\sin\delta_0\,\Delta e-pG(p)\,\Delta E\\
&-\omega_0x_d(p)\,\Delta i_d-(px_q(p)+r)\,\Delta i_q+\\
&(\psi_{d0}p+e_{d0})\,\Delta\delta=+\cos\delta_0\,\Delta e-\omega_0G(p)\,\Delta E\\
&-(\psi_{q0}+i_{q0}x_d(p))\,\Delta i_d+(\psi_{d0}+i_{d0}x_q(p))\times\\
&\qquad\Delta i_q+Mp^2\,\Delta\delta=\Delta T-i_{q0}G(p)\,\Delta E
\end{aligned}\right\}\quad(5)$$

Hollow Pipes of Relatively Small Dimensions

W. L. BARROW

Summary

SEVERAL cross sectional shapes for hollow-pipe transmission lines are described that provide lower operating frequencies for given outside dimensions than do the simple shapes heretofore proposed. The theory for one such line, the "septate coaxial cable" is derived, and experiments are reported. Cavity resonator embodying these principles are also described.

Introduction

The hollow-pipe type of conductor[1,2] for ultrahigh-frequency electromagnetic energy, although possessing several desirable features, has the disadvantage that its transverse dimensions are relatively large; namely, of magnitude comparable to the wave length. The object of this paper is to lessen this encumbrance by describing pipes that have transverse dimensions several times smaller than those of the simple forms previously proposed.*

The principle underlying the improved conductors derives from the properties of the $H_{0,1}$-waves[3] in a pipe of flat rectangular cross section, figure 1*A*. In this case, the critical wave length λ_0, i.e. the wave length above which no transmission takes place, is independent of d and depends on l only ($\lambda_0 = 2l$). By bending or folding the pipe transversely, keeping the separation between the top and bottom sides unchanged, a hollow conductor of smaller over-all dimensions may be obtained that has the same general internal configuration as the rectangular pipe. The deformation of the cross section may take place in a number of ways, several of which are shown in figure 1*B* to *D*. In the illustrations, the corresponding dimension l is indicated by a dotted line. In each of the deformed conductors there is a type of wave with a critical frequency approximately equal to $2l$, but the over-all dimensions of the deformed pipe are considerably smaller than those of 1*A* or of a circular pipe of the same critical value.

The conductor 1*B* may be thought of as a concentric line in which the center conductor is connected to and supported from the outer conductor along its entire length by a conducting radial rib or strip. Dielectric supports and spacers are unnecessary and the system is a uniconductor. Transmission in this particular example of the deformed pipes, which is here termed the *septate coaxial cable*, has been analyzed theoretically. Experiments have been made on it and on the partitioned rectangular type of 1*D*. The remainder of the paper presents the more important results of this research.

Theory of the Septate Coaxial Cable

The cylindrical co-ordinate system θ, r, x, in which x is the longitudinal co-ordinate, is indicated in figure 1*C*. A variation of all field components with the time t and with x of the form $e^{-hx+i\omega t}$ will be assumed, where h is the propagation constant, $\omega = 2\pi$ times frequency and $i = \sqrt{-1}$. The propagation constant for a pipe with a perfectly conducting wall is $i\beta$, where β is the phase constant. The attenuation constant α will not be given in this paper; although laborious, it may be calculated by known methods. The interior of the pipe has the dielectric constant ϵ, which is $10^{-11}/36\pi$ farads per centimeter for vacuum, air, and other gases that are primarily of interest for practical applications, and the permeability μ which is $4\pi \times 10^{-9}$ henries per centimeter for vacuum or gas.

The analysis begins with the wave equation in cylindrical co-ordinates, which is used to obtain solutions for the longitudinal field components E_x or H_x:

$$\left.\begin{matrix} E_x \\ H_x \end{matrix}\right\} = \sin(k\theta + C_3)\left\{C_1 J_k\left(r\sqrt{h^2+\left(\frac{\omega}{c}\right)^2}\right) + C_2 Y_k\left(r\sqrt{h^2+\left(\frac{\omega}{c}\right)^2}\right)\right\} e^{-hx+i\omega t} \qquad (1)$$

J_k and Y_k are Bessel functions of first and second kind, respectively, and of order k; the constant $C_1, \ldots C_3$ and the quantities k and h are determined from

Paper 41-8, recommended by the AIEE committee on communication and presented at the AIEE winter convention, New York, N. Y., January 27–31, 1941. Manuscript submitted November 5, 1938; made available for preprinting November 4, 1940.

Much of the analytical and the experimental work of this paper was carried out in the Master's Thesis "Electromagnetic Waves in Longitudinally Partitioned Hollow Pipes," by H. Schaevitz, M.I.T., 1938.

W. L. BARROW is assistant professor of electrical communications, Massachusetts Institute of Technology, Cambridge, and H. SCHAEVITZ is junior electrical engineer, Philadelphia Navy Yard, Philadelphia, Pa.

[1] For all numbered references, see list at end of paper.

* It is known that the dimensions of an ordinary hollow-pipe conductor may be reduced by filling its interior with a substance of dielectric constant substantially greater than unity. This method, however, introduces large losses because of the imperfectness of available dielectrics. The type of cables described herein accomplish the same result without incurring such dielectric losses. They will also effect a further reduction of dimensions in the dielectric filled pipes.

---

and equation 3 reduces to

$$\begin{aligned} D = Mp^2[(px_d(p)+r)(px_q(p)+r)+ \\ \omega_0^2 x_q(p)x_d(p)] + (\psi_{d0} + i_{d0}x_q(p)) \times \\ [(px_d(p)+r)(\psi_{d0}p+e_{d0})+ \\ \omega_0 x_d(p)(\psi_{q0}p+e_{q0})] + (\psi_{q0}+i_{q0}x_d(p)) \times \\ [-\omega_0 x_q(p)(\psi_{d0}p+e_{d0})+ \\ (px_q(p)+r)(\psi_{q0}p+e_{q0})] \end{aligned} \qquad (6)$$

boundary conditions. The other components of field are obtained from (1) by means of Maxwell's equations. Two different kinds of solutions exist: one, in which $H_z=0$, corresponding to hollow-pipe waves of the E type; and the other, in which $E_z=0$, corresponding to hollow-pipe waves of the H type. In each instance, the boundary conditions for a perfectly conducting wall, i.e., the vanishing of the tangential component of electric field on all surfaces of the conductor, are next imposed on the solutions. A transcendental equation for the propagation constant h results, the solution for which allows the critical frequency, wave length and the other transmission properties to be calculated.

E$_{n,m}$-WAVES

We place $H_z=0$ and derive the other field components from E_z in (1). The boundary condition requires $E_z=0$ for $\theta=0$, θ_0 and $r=a$, b. We find that $C_3=0$ and $k=n\pi/\theta_0$, where $n=1, 2 \ldots$ and that the field is given by:

$$\left.\begin{aligned}
E_z &= \sin k\theta\cdot G\cdot e^{-hz+i\omega t}\\
E_\theta &= \frac{-hk}{r\left[h^2+\left(\frac{\omega}{c}\right)^2\right]}\cos k\theta\cdot G\cdot e^{-hz+i\omega t}\\
E_r &= \frac{-h}{h^2+\left(\frac{\omega}{c}\right)^2}\sin k\theta\cdot\frac{dG}{dr}\cdot e^{-hz+i\omega t}\\
H_\theta &= \frac{i\omega\epsilon}{h^2+\left(\frac{\omega}{c}\right)^2}\sin k\theta\cdot\frac{dG}{dr}\cdot e^{-hz+i\omega t}\\
H_r &= \frac{i\omega\epsilon k}{r\left[h^2+\left(\frac{\omega}{c}\right)^2\right]}\cos k\theta\cdot G\cdot e^{-hz+i\omega t}\\
H_z &= 0\\
&\text{where}\\
G &= C_1J_k\left(r\sqrt{h_2+\left(\frac{\omega}{c}\right)^2}\right)+\\
&\qquad C_2Y_k\left(r\sqrt{h^2+\left(\frac{\omega}{c}\right)^2}\right)
\end{aligned}\right\}\quad(2)$$

The transcendental equation for h is:

$$\frac{J_k\left(a\sqrt{h^2+\left(\frac{\omega}{c}\right)^2}\right)}{Y_k\left(a\sqrt{h^2+\left(\frac{\omega}{c}\right)^2}\right)}=\frac{J_k\left(b\sqrt{h^2+\left(\frac{\omega}{c}\right)^2}\right)}{Y_k\left(b\sqrt{h^2+\left(\frac{\omega}{c}\right)^2}\right)}\quad(3)$$

This equation may be solved approximately by means of McMahon's series[4] to get β, where $h=i\beta$:

$$\beta=\sqrt{\left(\frac{\omega}{c}\right)^2-\left[\frac{m\pi}{b-a}+\frac{(4\pi^2n^2-\theta_0^2)(b-a)}{8abm\pi\theta_0^2}+\ldots\right]^2}\quad(4)$$

where $m=1, 2, 3 \ldots\ldots$

The critical frequency is the root of the equation $\beta=0$:

$$f_0=\frac{c}{2\pi}\left[\frac{m\pi}{b-a}+\frac{(4\pi^2n^2-\theta_0^2)(b-a)}{8abm\pi\theta_0^2}+\ldots\right]\quad(5)$$

The transmission characteristics may be found in the usual way: Wave length in pipe $=\lambda_p=\frac{2\pi}{\beta}$; phase velocity $=v_p=\frac{\omega}{\beta}$; group velocity $=v_g=\frac{d\omega}{d\beta}$.

In the septate coaxial cable, $\theta_0=2\pi$. For the special case of $n=1$, k becomes 1/2 and J_k and Y_k reduce to the following form:

$$\left.\begin{aligned}
J_{1/2}(x) &= \sqrt{\frac{2}{\pi x}}\sin x\\
Y_{1/2}(x) &= \sqrt{\frac{2}{\pi x}}\cos x\\
&\text{where}\\
x &= r\sqrt{h^2+\left(\frac{\omega}{c}\right)^2}
\end{aligned}\right\}\quad(6)$$

Consequently, the phase constant becomes

$$\left.\begin{aligned}
\beta &= \sqrt{\left(\frac{\omega}{c}\right)^2-\left(\frac{m\pi}{b-a}\right)^2}\\
&\text{and}\\
\lambda_0 &= \frac{2(b-a)}{m}
\end{aligned}\right\}\quad(7)$$

For $m=1$, the critical wave length is equal to twice the radial distance between the outer and inner circular walls; this result bears a striking similarity to the H$_{1,0}$-wave in a rectangular pipe.

The electric intensity in the transverse cross section is given by:

E$_{1,m}$-WAVE

$$\left.\begin{aligned}
E_r &=\\
&\frac{C_4}{\sqrt{r}}\sin\frac{\theta}{2}\left[\frac{m\pi}{b-a}\cos\left(\frac{m\pi}{b-a}r-C_5\right)-\right.\\
&\qquad\left.\frac{1}{2r}\sin\left(\frac{m}{b-a}r-C_5\right)\right]e^{-hz+i\omega t}\\
E_\theta &= \frac{C_4}{2r\sqrt{r}}\times\\
&\qquad\cos\frac{\theta}{2}\sin\left(\frac{m\pi}{b-a}r+C_5\right)e^{-hz+i\omega t}
\end{aligned}\right\}\quad(8)$$

where C_4 and C_5 are new constants.

Sketches of the field configurations of the $E_{1,1}$-wave and the $E_{2,1}$-wave in the transverse section are shown in figure 2. It is apparent that higher order E-waves may be considered as built up from $E_{1,1}$-waves. We observe that in the $E_{2,1}$-wave a second septum may be placed within the pipe at $\theta=\pi$, providing two independent and separate hollow-pipe channels having the same critical frequency as that of the $E_{2,1}$-wave in the septate coaxial line. This idea has been suggested by Schelkunoff.[5] Figure 3 illustrates the relations between the ratio of the critical wave length to the radius of the outer tube, λ_0/b, and the angular dimension θ_0; evidently the longest critical wave length is afforded by $\theta_0=2\pi$, that is, by the septate coaxial line. The critical wave length increases with increasing b/a, as is also illustrated in figure 3.

H$_{n,m}$-WAVES

We place $E_z=0$ and derive the remaining field components from H_z in (1), obtaining:

$$\left.\begin{aligned}
H_z &= \cos\left(\frac{n\pi}{\theta_0}\theta\right)\cdot G\cdot e^{-hz+i\omega t}\\
H_\theta &= \frac{h\frac{n\pi}{\theta_0}}{r\left[h^2+\left(\frac{\omega}{c}\right)^2\right]}\sin\left(\frac{n\pi}{\theta_0}\theta\right)\cdot G\cdot e^{-hz+i\omega t}\\
H_r &= \frac{-h}{h^2+\left(\frac{\omega}{c}\right)^2}\cos\left(\frac{n\pi}{\theta_0}\theta\right)\frac{dG}{dr}\cdot e^{-hz+i\omega t}\\
E_\theta &= \frac{i\omega\mu}{h^2+\left(\frac{\omega}{c}\right)^2}\cos\left(\frac{n\pi}{\theta_0}\theta\right)\cdot\frac{dG}{dr}\cdot e^{-hz+i\omega t}\\
E_r &= \frac{i\omega\mu\frac{n\pi}{\theta_0}}{r\left[h^2+\left(\frac{\omega}{c}\right)^2\right]}\sin\left(\frac{n\pi}{\theta_0}\theta\right)\cdot G\cdot e^{-hz+i\omega t}
\end{aligned}\right\}\quad(9)$$

where h and G have the same meaning as before. The transcendental equation for h is now

$$\frac{J_k'\left(a\sqrt{h^2+\left(\frac{\omega}{c}\right)^2}\right)}{Y_k'\left(a\sqrt{h^2+\left(\frac{\omega}{c}\right)^2}\right)}=\frac{J_k'\left(b\sqrt{h^2+\left(\frac{\omega}{c}\right)^2}\right)}{Y_k'\left(b\sqrt{h^2+\left(\frac{\omega}{c}\right)^2}\right)}\quad(10)$$

The approximate solution of (10) provides the values:

$$\left.\begin{aligned}
\beta &= \sqrt{\left(\frac{\omega}{c}\right)^2-\left[\frac{m}{b-a}+\frac{(4\pi^2n^2+3\theta_0^2)(b-a)}{8abm\pi\theta_0^2}+\ldots\ldots\right]^2}\\
f_0 &= \frac{c}{2\pi}\left[\frac{m\pi}{b-a}+\frac{(4\pi^2n^2+3\theta_0^2)(b-a)}{8abm\pi\theta_0^2}+\ldots\ldots\right]
\end{aligned}\right\}\quad(11)$$

A sketch of the field configuration of the H$_{0,1}$-wave is reproduced in figure 2. In this wave, there is only one component of electric intensity, namely in the angular direction, and this component varies approximately as a half-sinusoid radially. A comparison of (11) with (4) and (5) shows that the critical frequency has the same functional form as that for the *E*-wave.

$H_{1,0}$-WAVES

If we let $\theta_0 \to 0$ as $a \to b \to \infty$, the cross section of the pipe approaches a rectangle, and consequently there must be a wave in the septate coaxial cable which will degenerate into the $H_{n,0}$-wave in the rectangular pipe. Thus there is reason to believe that an approximate solution may be obtained for $m=0$ even though (1) is not strictly valid for this value of *m*. Calculations are possible by graphical methods for the special case $n=1$ and $\theta_0=2\pi$. For this case $k=1/2$, and

$$G=\sqrt{\frac{2}{\pi r\sqrt{h^2+\left(\frac{\omega}{c}\right)^2}}}\left[C_1\sin\left(r\sqrt{h^2+\left(\frac{\omega}{c}\right)^2}\right)-C_2\cos\left(r\sqrt{h^2+\left(\frac{\omega}{c}\right)^2}\right)\right] \quad (12)$$

After applying the boundary condition $\frac{dG}{dr}=0$ for $r=a$, b and simplifying we obtain the following transcendental equation for *h:*

$$\tan\left[(b-a)\sqrt{h^2+\left(\frac{\omega}{c}\right)^2}\right]=\frac{2(b-a)\sqrt{h^2+\left(\frac{\omega}{c}\right)^2}}{1+4ab\left[h^2+\left(\frac{\omega}{c}\right)^2\right]} \quad (13)$$

This equation has been solved by graphical means for specific ratios of *a* and *b*. The constant β and λ_0 can be found in the usual way.

The importance of this wave is that it has the lowest critical frequency of any wave in a septate coaxial line. To illustrate this point, let us consider the case in which $a \to b$. Equation 13 then becomes simply

$$\sqrt{h^2+\left(\frac{\omega}{c}\right)^2}=\frac{1}{2b}$$

i.e.

$$\beta=\sqrt{\left(\frac{\omega}{c}\right)^2-\left(\frac{1}{2b}\right)^2} \quad (14)$$

and the corresponding critical wave length is:

$$\lambda_0=2\cdot 2\pi b \quad (15)$$

that is, the critical wave length is twice the circumference of the pipe. The longest critical wave length in a rectangular pipe is twice the width of the pipe, and the longest critical wave length in a circular pipe is 3.41 times the radius. Thus, *the limiting critical wave length of the septate line is greater than that of a circular hollow*

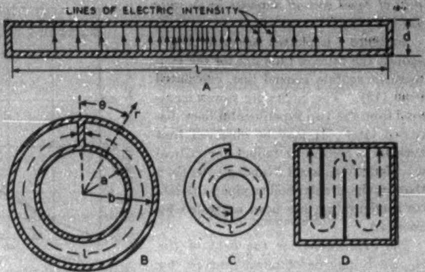

Figure 1. Transverse cross sections of several shapes of hollow pipes; (A) flat rectangular, (B) septate coaxial, (C) spiral, (D) folded. The critical frequencies are approximately the same for each pipe

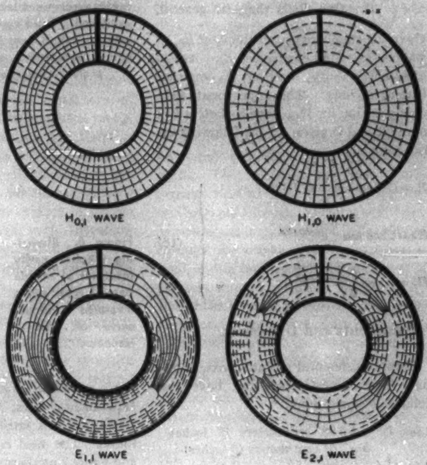

Figure 2. Configuration of the electric field intensity for four types of waves in a septate coaxial cable

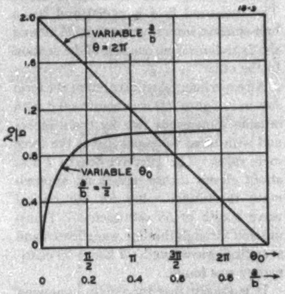
Figure 3 (below). $E_{1,1}$ wave. Relative critical wave length λ_0/b versus a/b in a septate coaxial cable ($\theta_0=2\pi$), and λ_0/b versus θ_0 for a/b = 1/2



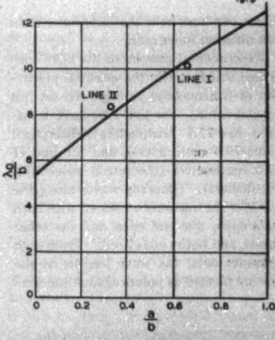


Figure 4. $H_{1,0}$ wave in septate coaxial cable. Relative critical wave length λ_0/b versus a/b. The small circles indicate measured values from two experimental cables

pipe of equal over-all diameter by the ratio $4\pi/3.41 = 3.68$.

In figure 4 is plotted the ratio of λ_0/b against the ratio of radii a/b for the $H_{1,\theta}$-wave in septate coaxial line, calculated from (13). The circles are values measured from the two experimental lines discussed later. It may be observed that even for a zero inner radius, the critical wave length is about 1.5 times greater than that for the circular hollow pipe; this latter configuration has been suggested by Sonoda.[6]

The expressions for the field of the $H_{1,\theta}$-wave may be obtained from (9) by substituting the appropriate values for $h^2+\left(\frac{\omega}{c}\right)^2$. One finds that, in general, there is a small angular component E_θ, as well as the radial component E_r. As b/a approaches unity, however, E_θ vanishes leaving E_r only. This approximate field configuration for $H_{1,\theta}$-wave is sketched in figure 2 and is given by the following expressions:

$$\left.\begin{aligned} E_r &= C2i\omega\mu b \sin\frac{\theta}{2}\, e^{-hz+i\omega t} \\ H_\theta &= C2hb \sin\frac{\theta}{2}\, e^{-hz+i\omega t} \\ H_z &= C \cos\frac{\theta}{2}\, e^{-hz+i\omega t} \end{aligned}\right\} \qquad (16)$$

Experiments and Discussion

Two experimental septate coaxial lines have been investigated that have the following dimensions:

Line I: $a = 5.08$ centimeters (2 inches)
$b = 7.62$ centimeters (3 inches)

Line II: $a = 2.54$ centimeters (1 inch)
$b = 7.62$ centimeters (3 inches)

These two lines have the same outer radii but different inner radii.

Experimental measurements have confirmed satisfactorily the essential properties of transmission through the septate coaxial cable. For line I we have measured $\lambda_0 = 77.5$ centimeters (theoretical value 79.5 centimeters), and for line II 63.5 centimeters (theoretical value 61.3 centimeters). Standing waves along the inside of the line were measured with both ends open, one end open and the other closed, and both ends closed. From such measurements, the wave lengths on the line are plotted as points against the free-space wave lengths in figure 5 for the two experimental lines; the solid curves are theoretical. A satisfactory agreement is found. The field configuration of (16) and figure 2 has been verified by measurements with a small "probe" antenna. The measured field is radial and has a half-sinusoid intensity distribution around the 2π radians from one side of the septum to the other.

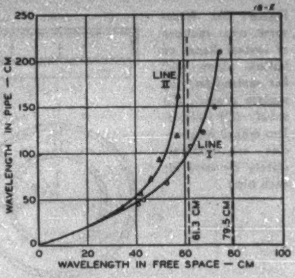

Figure 5. Wave length in two septate coaxial cables versus wave length in free space of the excitation. Solid curves give the theoretical values; dotted lines indicate the theoretical critical wave length, and the circles and triangles represent experimental values

An experimental septate line of the form shown in figure 1*D* was constructed with outside dimensions two by three inches and with three vanes parallel to the three inch sides. The effective length l was about eleven inches, giving an approximate theoretical value for the critical wave length of 55 centimeters. Transmission through this line was effected and a critical wave length of about 50 centimeters was found.

It is known that the cavity contained within a section of hollow pipe closed at both ends manifests pronounced resonance characteristics.[1,3] A highly effective or "high Q" resonator for use in conventional circuits is provided by such a cavity when a connection to the cavity is made by inserting a short length of wire into the cavity through a small hole. Septate lines are readily adapted to this use and offer the advantage of a relatively low resonant frequency for given over-all dimensions. Figure 6 shows a resonator of this kind and a measured response curve obtained in a cavity established in the experimental line II between transverse sheet-metal annuli. Improved construction would improve markedly the sharpness of resonance. The sketch of figure 6 will also serve to show one method of connecting a septate-line terminal to conventional sending or receiving apparatus. Another cavity resonator based on the same principles and providing, too, a relatively long resonant wave length comprises two concentric metal spheroids connected together by a single radial metal rod, which may also serve as a supporting member for the inner spheroid.

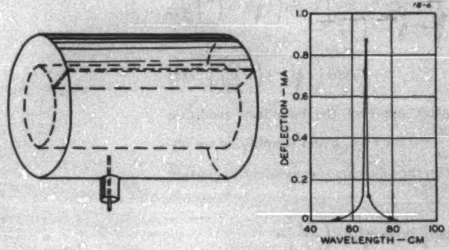

Figure 6. Illustrating a hollow cavity resonator of septate coaxial type and a measured response curve of such a resonator

Impulse and 60-Cycle Characteristics of Driven Grounds

P. L. BELLASCHI
FELLOW AIEE

I. Introduction

DRIVEN grounds are important in electric power transmission and distribution. In fact, they comprise one of the essential elements in the art of lightning protection. Yet, to this day, the value of protection derived from grounds under actual operating conditions of lightning discharge is difficult to state in full quantitative measure. And the reason for this situation lies partly in the lack of fundamental knowledge of the impulse characteristics of driven grounds. In part, the difficulty also is due to the complex factors that inherently make up driven grounds and ground systems.

A comprehensive survey of principles and methods on driven grounds was issued in 1918 by the Bureau of Standards.[1] Further contributions have appeared since, some presenting new developments and findings,[2] others dealing on theoretical aspects of the problem,[3] and a third group bearing on related questions.[4] In recent years, progress has been centered on the immediate field of application. Here the emphasis has been to obtain effective service with such methods of grounding as lend themselves particularly to economical installation. For instance, a common practice with some utilities nowadays is to drive rods to considerable depths, even down to bedrock, so as to attain the lowest measurable resistance. A recognized practice for securing low-resistance grounds is also to place a sufficient number of electrodes in parallel (multiple grounds). Still another expedient is that of reducing the resistivity of the soil immediately surrounding the electrode by suitable treatment with common salt (NaCl) or other conducting solution. All these developments have been based largely either on 60-cycle values or on closely similar methods of testing. And from the measured 60-cycle values plus what experience would ensue there have been established present practices.

It is a fact that the 60-cycle methods of measurement have the great merit of simplicity[5,6] and it is conceded that experience can often rationalize methods of evaluating performance that are not altogether fundamental. Yet the need of establishing the performance of grounds under the actual service conditions of lightning discharge has long been recognized. In this connection, the tests by H. W. Towne[7] in 1928 and more recently an investigation by H. Norinder[8] has contributed to point out the significance of the impulse characteristics of driven grounds—even though both investigations are somewhat limited in scope considering the extent and practical importance of the subject.

Those versed in the art know that the impulse resistance of a driven ground is below the corresponding megger or 60-cycle measured values. The practice usually followed, to consider the megger values as a basis for design, is also a recognition of this fact. There are other factors which affect design and economy of installation, but these need not be gone into at this time. An immediate fundamental need is for impulse data on actual driven grounds, under impulse currents well approaching lightning conditions. The results of the investigation presented in this paper should therefore be timely and helpful to the art of lightning protection.

II. Test Arrangement

The Sharon High-Voltage Laboratory is located in the open. This is a favorable circumstance that has facilitated the investigation, for the grounds can be driven in the natural soil within easy reach of a well-equipped impulse laboratory. The arrangement that was used is shown in figure 1.

The impulse generator and the instruments are grounded to the common, low-resistance grid of the laboratory, which measured with the megger 0.9 ohm to earth. The voltages of the driven grounds were recorded at the cathode-ray oscillograph through a voltage divider. Likewise the impulse currents discharged through the driven grounds were measured at the oscillograph, by means of a suitable shunt inserted in the grounded end of the impulse generator. The technique of testing and measurement complies essentially with the recognized methods described in AIEE Standards No. 4 (1940) and in the literature. Other details on the test arrangement will be apparent from figure 1 and the following.

III. Physical Characteristics of Driven Grounds

Four one-inch diameter steel rods, designated as *A*, *B*, *C*, and *D* in figures 1 and 2, were driven in the natural soil outside the laboratory in 1933. They have been in the soil ever since. Two of the rods were driven nine feet in the earth, the other two struck rocks at seven and one-half feet and could not be driven deeper. Early in 1940, after this investigation, two of the rods were removed for inspection. There was no evidence of rusting of the metal at the surface in contact with the soil.

The soil of the grounds is a combination of shale and clay with a mixture of gravel and sand. The earth is normally moist in this location. The physical nature of the soil became more apparent from the examination of a six-foot diameter ten-foot deep hole that was dug in May 1940 near the laboratory at about 25 feet from the location of the grounds. First, sev-

eral inches of vegetation soil was removed. Then a combination of clay, sand, and gravel followed to a depth of five feet. In fact a strata of about a foot consisted of a compact layer of gravel and rocks. From five feet down to ten feet, the bottom of the hole, the soil consisted of a thick blue clay. In digging the hole, water started seeping in at a depth of three feet. A rod consisting of multiple sections was driven straight down in the field nearby. It struck solid bedrock at 30 feet. Still other details of the terrain and adjacent objects will be apparent from figures 1 and 2. In short, the class and the nature of the soil are quite typical of conditions that are encountered in Western Pennsylvania and also in other sections of the country.

IV. Tests

(*A*). First series. These tests were completed in November 1939 before the ground had frozen at all. The winter in 1939–1940 got under way late in Western Pennsylvania. Sixty-cycle values for the four driven grounds and for combinations of them are summed up in table I. The voltmeter-ammeter method with sinusoidal waves was applied in these and later tests. Currents ranged from one to five amperes and in one case up to ten amperes. Within these limits the resistance is found to decrease two to three per cent with increase in the current.

* Corresponding readings of rms and avg voltmeters all agree within 1.5 per cent.

The results of the impulse tests which were made at this same time are summarized in table II. The footnote describes the arrangement of the generator. A 6x13 microsecond wave and currents (crest) from 2,000 to 8,000 amperes were applied in these tests. Figure 3-*AF* is a typical oscillogram. The seventh column of table II is of particular interest as it gives the ratio of the impulse to the 60-cycle resistance for the impulse currents discharged through the grounds. The tabulation reveals other points of practical interest. For instance, the presence of a metal fence and a fill-in of coke and cinder adjacent to rods *A* and *B* (figure 2) affected the impulse characteristics of these grounds, particularly at the higher currents. This illustrates the various considerations that require attention when establishing grounds.

(*B*). Second series. The second series of tests was made in January 1940. By this time the ground had frozen at the surface six or eight inches and the temperature had dropped. The resistance had accordingly increased about ten per cent. Through the assistance of the local utility (Pennsylvania Power Company), megger readings of the grounds were taken. These with the 60-cycle values are reported in table III.

The impulse data are summarized in table IV. In these tests, the generator was set for a 12x50 microsecond wave and currents (crest) from 700 to 6,500 amperes were available. Typical oscillograms of the current and the voltage are shown in *AX* and *BJ* of figure 3. In the next to the last column of table IV is reported the ratio of the impulse to the 60-cycle resistance for these tests. Again when the two grounds adjacent to the fence, particularly rod *A*, were tested at the higher currents, surface flashover and apparent breakdown in the earth took place. The oscillograms of *BT* (figure 3) illustrate this effect.

(*C*). Other tests. Sixty-cycle check tests on the grounds were made in the summer (1940). They are reported in table III. The data in this table thus show the seasonal variation of the ground resistances.

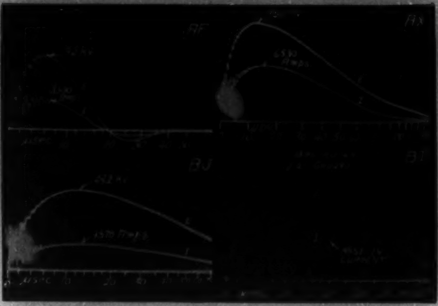
V. Impulse and 60-Cycle Characteristics

As shown in figure 4, a definite relation holds between the ratio of the impulse to the 60-cycle resistance and the impulse current. The values plotted are for the tests on grounds *C*, *D*, *B*, and the combination *C* and *D* (tables II and IV). The test data are for 6x13 microsecond and 12x50 microsecond waves, but it appears reasonable that the curve applies for impulses over a wider range of waves as encountered in the field. It should be noted that successive applications or tests repeated at different times did not affect the ratio, other than an amount due to inherent variations.

In rounded figures the ratio for these grounds at 1,000, 2,500, 5,000 and 10,000 amperes decreases respectively to the values 0.85, 0.75, 0.65, and 0.55. At higher currents, as 20,000 amperes—provided the potentials developed can be sustained by the grounds, from extrapolation of the curve the ratio does not seem to come materially below 0.50. A lightning stroke to a distribution or a transmission circuit or to a lightning-rod system in general is likely to discharge to earth through more than one path to ground. Therefore the range of currents in figure 4 covers field conditions from a traveling surge to a direct stroke of lightning.

Two factors in particular governed the low impulse breakdown from rod *A* to the adjacent wire fence. Rod *A* was driven eight and one-half feet from the fence, but what seems to have been even a greater influencing factor was the presence of a fill-in of coke and cinders on the ground layer from the fence to the rod. The relative proximity to rod *A* affected rod *B* somewhat, but only at the higher currents. Rods *C* and *D* on the other hand were amply removed from adjacent bodies and were well surrounded by homogeneous and natural soil, with the result that they sustained the impulse voltages up to the top limit of the test. The performance of rod *A* illustrates emphatically that other considerations govern the installation of grounds besides those dictated by 60-cycle measurements alone.

Figure 3. Typical oscillograms of impulse voltages (E) and currents (I)



The 60-cycle resistance for the various parallel combinations of the four rods (table III) is approximately the amount expected from calculation[3] or from previous studies.[1] For example, *A* and *B* in parallel calculates 29 ohms, *B* and *D* 24.5 ohms and *A*, *B*, *C*, and *D* 18.5 ohms. Rods *C* and *D* in parallel show no reduction due in part to the close proximity of the electrodes and possibly to other factors residing in the earth. However, grounds *C* and *D* were good grounds to test with as these were in natural and homogeneous earth, uninfluenced by extraneous bodies and least affected by seasonal variations such as result from changes of the temperature and moisture content in the earth (table III).

For parallel grounds liberally spaced and of normal characteristics, the ratio of impulse to 60-cycle resistance for the individual grounds should hold adequately close for the parallel combination when applied on the basis of the current per rod. The only data available to corroborate this point are the impulse tests on *B* and *D* in parallel (table IV).

A characteristic fundamentally significant is the variation of the resistance of grounds during the impulse discharge. For instance, from the voltage and current oscillograms of *BJ* in figure 3, the resistance from ten to fifty microseconds is found to average 31.5 ohms within about one per cent. Other typical oscillograms are analyzed in table V. The grounds of this investigation exhibited markedly constant resistance, usually within a ten per cent variation, over the part of the discharge that can be considered of more practical significance, i.e., for currents above 50 per cent crest. The relatively constant value of the impulse resistance is apparent also from figure 4 which shows that for a given

current (crest) of the characteristic the ratio does not increase more than 15 per cent at a current (crest) half that value. It is of interest to note that the crest voltage developed precedes the crest current one or two microseconds. As the current recedes on the tail of the wave, the resistance increases (table V). A similar analysis at the lower currents on the front was not possible on account of the superimposed oscillations present in this part of the oscillograms.

The process of the variation of resistance with the current discharge becomes more apparent from the ratio of the impulse to the 60-cycle resistance during the discharge, when referred to the characteristic of figure 4. The ratios of typical oscillograms (table V) are plotted in figure 5 along with the characteristic. Consider oscillograms *AW* and *BR*. As indicated by the arrows in figure 5, as the current rises on the front and approaches crest, the ratio follows the characteristic in a downward trend. When the current reaches crest and then recedes on the tail, the ratio retraces back under the curve traced for the rising part of the current. With further drop of the current the ratio continues to rise, following the characteristic upward. As the case of oscillogram *AS* shows, impulse currents of lower amplitude likewise trace paths that follow near along the characteristic.

While the nature of the oscillograms does not permit complete analysis from the beginning of the front (first few microseconds), yet it is clear from the foregoing that the mechanism of the impulse current discharge for the grounds tested is as follows. The ratio of the impulse to the 60-cycle resistance as the current rises on the front follows in good measure the characteristic (figure 4), down to the value corresponding to the crest current which lies on the characteristic. As the current recedes on the tail the ratio traces a loop under the characteristic for an impulse of high current. Apparently ionized paths or similar effects established by the discharge account for the relatively constant resistance at currents of the discharge above fifty per cent of the crest. As the current drops further, the ratio swings upward with the characteristic. As the lowest current values are reached, a residual voltage may even be present (see *AX* in figure 3).

Though the voltage of driven grounds is usually considered as a resistance drop, some inductance drop is present also. In most cases, however, the inductance of the ground proper is practically unimportant, unless the current rises or recedes unusually abruptly or in the case rods are driven to considerable depth. For each of the driven rods employed in this investigation, the inductance is approximately three microhenrys and even then only a part is effective since the current diminishes along the rod. The time constant (L/R) of the grounds is then less than 0.1 microsecond. Thus for a current rising exponentially to crest in five microseconds, the ohmic drop (Ri) at 2.5

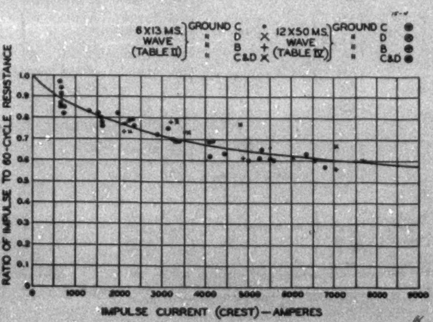

Figure 4. Characteristic of driven grounds: ratio of impulse to 60-cycle resistance versus impulse current (crest)

microseconds is 97 per cent of the impedance drop $(Ri+Ldi/dt)$ and as the wave progresses beyond the two merge together since the inductive drop practically disappears. On the other hand it should be amply clear that the inductive effect of leads or in the tower structure that connect the ground proper to the point of incidence of the lightning stroke may be a factor of primary importance in lightning protection.

VII. Discussion of Results

The characteristic of figure 4 applies for a soil of medium resistivity, that is a soil consisting largely of clay with some gravel, etc. The same rods driven in other soils would likely be governed by curves of the same general character, but of different slope. Towne in his investigation[7] on 0.84-inch diameter pipes driven into loose, gravelly soil (artificial fill) obtained ratios from 0.80 to 0.34 for currents (30 x 120 microsecond wave) well under 1,000 amperes. A single ten-foot driven-pipe ground which measured 82 ohms on 60-cycle had a resistance of 50 ohms at 660 amperes—that is a ratio of 0.61. McEachron, Hemstreet, and Rudge in their field tests[8] reported for a pipe driven into the ground, which measured 180 ohms with the megger, a ratio of 0.67 at 550 amperes—the highest impulse current applied. For a 1.3 inch pipe driven four feet into natural soil consisting largely of clay, Norinder found a ratio of 0.76 corresponding to a current of approximately 1,000 amperes. It is of interest to note that in his other tests[8] where the impulse resistance was determined for both positive and negative polarities, the difference found practically was small. In this investigation (tables II and IV) positive impulse currents were applied. In short, it is clear that characteristic curves similar to figure 4 for other typical soils such as sand, etc., obviously are desirable.

Future investigations on high and low resistivity soils may furthermore shed light also on the physical processes that determine the decrease in resistance with increase in current. The present explanation, borne out by this and the investigations cited, is that "the decrease in resistance is probably due to high-resistance contacts between the more conducting particles of soil, at or near the surface of the electrode, which are bridged over by arcs or sparks when sufficient voltage is applied." For instance, the resistivity of the soil at the low 60-cycle currents for grounds *C* and *D* (table III) in the order of 7,500 ohms per cubic centimeter. On the basis of this resistivity the voltage gradient at the rod, when discharging an impulse current of 10,000 amperes (crest), would be $10{,}000 \times 7{,}500/\pi \times 90 \times 6.45$, i.e., 41 kilovolts per centimeter. It is doubtful whether grounds could sustain gradients of this magnitude at all without breakdown. As a matter of fact, from figure 4, the average resistivity of the soil at 10,000 amperes is 0.55 the 60-cycle value to which there corresponds a gradient of 22.5 kilovolts per centimeter. Actually the effective resistivity of the soil at the rod is even less, and the voltage gradient at the rod is correspondingly lower. Studies of the gradients developed should contribute to a better understanding of driven grounds.

Another factor which determines the characteristic of grounds is the size, form, and arrangement of the electrode. Besides rods and pipes, other common types

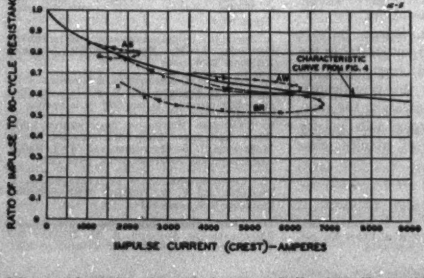

Figure 5. Variation of "impulse resistance to 60-cycle resistance" ratio during impulse current discharge compared with characteristic (figure 4)

Minimum Insulation Level for Lightning Protection of Medium-Voltage Lines

H. N. EKVALL
ASSOCIATE AIEE

LIGHTNING protection of wood pole lines is a problem of wide interest among operating companies. It is therefore timely to cite the experience of the Philadelphia Electric Company during the six year period, 1935–40, in successfully renovizing its 13 and 33 kv wood pole lines to reduce trouble.

In 1935 this company was faced with the problem of determining how to materially reduce lightning trouble on a variety of pole top configurations at a minimum of expense. It had been shown by Andrews and Stroup[1] that wood insulation could be employed effectively. However, no information was available to indicate what reduction in trouble could be obtained for various increases in insulation. The high ridge pin configuration proposed by these authors, while reported to be very effective, could not be applied to many of the existing line structures without making major changes in construction at considerable expense. There was therefore need for an investigation into the degree of protection afforded by lesser amounts of insulation. With this problem in mind, the author set out to make a detailed investigation of the performance of the various types of structures and to correlate their insulation strength with their rate of trouble.

It was discovered from these correlations that substantial reductions in trouble occurred with increases in insulation strength up to a certain level and that equal increases above this level were much less effective. It was evident, therefore, that the greatest reduction in trouble, at least cost, could be obtained by improving those structures which were below the indicated level. As the result of these findings, minimum insulation levels were adopted for both the 13 and 33 kv systems and used as a basis for renovizing the lines. The levels adopted were somewhat below the insulation strength of the high ridge pin construction proposed by Andrews and Stroup.

Besides establishing a minimum insulation level on which to base construction practice, the data obtained were also found very helpful in predicting what reduction in trouble might be obtained from construction changes and thereby aided in justifying the expenditure required.

This paper describes the procedure followed in determining the susceptibility to lightning trouble of pole line structures of various insulation strengths, indicates what changes were made to structures below the required minimum level and shows what reduction in trouble was obtained by these changes on the 13 and 33 kv systems.

Description of Systems

The 13 kv lines investigated were those in Philadelphia. They are three wire three-phase circuits with the neutral grounded through a four ohm resistor at the generating stations and through a grounding transformer at one substation. Although operated as radial circuits, they form a network over the city with numerous breakdowns to each other through pole top air break switches. These lines have a total length of 125 circuit miles, and an average length per circuit of 2.6 miles.

The 33 kv lines are in the suburban territory covering an area of approximately 1,400 square miles surrounding Philadelphia. They are three wire three-phase circuits, with the neutral solidly

---

of grounds which serve to conduct lightning currents into the earth, are the footing of transmission-line towers and of other structures such as are found at substations, etc. In general, it appears from the preceding considerations and the test data that electrodes which contribute inherently to lower the current density in the soil are likely to influence the characteristic in a direction towards a more constant resistance with increase in current. The practical usefulness and basic importance in establishing characteristic curves for typical forms of ground electrodes need not be emphasized. Through such an approach the problems presented from grounds can be rationalized more readily and the value derived from grounds assessed in a more quantitative measure. An effective ground means greater safety in protection and an improved ground may mean reduced insulation or insulation clearances with the resulting benefit of reduced costs.

VII. Summary

This investigation presents test data on the impulse and 60-cycle characteristics of common rods driven in natural soil (largely clay composition). It sums up and analyzes the results in the characteristic curve of the ratio of impulse to 60-cycle resistance for impulse currents that represent conditions ranging from a traveling surge to direct strokes of lightning. The basic reasons for the performance of grounds to impulse currents as they do are pointed out insofar as the experimental data and observations permit to do so. From this investigation the desirability of establishing the characteristic for other typical soils and for other common types of grounds (electrodes) is apparent.

grounded at two points centrally located on the system. These lines are primarily connecting links between the suburban 33 kv-4 kv substations and have a total length of 460 circuit miles and an average length per circuit of 14.2 miles.

Basis for Protection

Experience on the lines of the Philadelphia Electric Company had shown that power arcs resulting from lightning flashovers were the principal source of trouble and that lightning itself seldom caused more than slight splintering of the pole or crossarm. It was concluded, therefore, that a good basis for protection would be one which minimized the chances for power arc formation. The method adopted was to lengthen the initial arc-over paths along the pole and crossarm by increasing the insulation between phases and between phase and ground.

In determining the insulation strength of the various types of structures it appeared desirable from the above experience to base it on factors directly influencing power arc formation. Two factors which appeared predominant were the length of insulation in the arc-over path and the 60 cycle voltage across the path. Accordingly, these terms were used as a basis for measurement of insulation strength.

Measurement of Insulation Length

At the beginning of this investigation, field surveys were conducted which showed that both the 13 and 33 kv systems had a large variety of pole top arrangements, resulting in a wide range of insulation lengths along the arc-over paths between phases and between phase and ground. It was therefore necessary to make all comparisons of power arc trouble on the basis of individual structures rather than on miles of line, as is frequently done. Accordingly detailed information was obtained for each pole indicating such things as length of crossarm, type of insulators and braces, location of line wires, guys, ground wires, and other pertinent data. From these data the length of insulation in the arc-over path between phases and between phase and ground was determined for each structure. In all, approximately 20,000 poles were investigated.

In each case the arc-over path was considered as being along the surface of the pole or crossarm rather than directly between wires in air. The length of insulation in the arc-over path was taken as the sum of the porcelain and wood insulation lengths. Parts of the crossarm or pole shunted by metallic hardware were excluded. The insulation length assigned to each pin type insulator was its wet arc-over distance as given by the manufacturer's catalog, while for a string of suspension insulators their insulation length was taken to be the wet arc-over of one unit plus the distance between centers of successive additional units. This was done because this distance is the length of the arc-over path after the lightning has flashed over the string.

The measurement of length of insulation in the arc-over path is illustrated in figures 1 and 2. In figure 1 the total length of insulation from phase *A* to phase *B* is 84 inches, and from phase *A* to ground *G* is 49 inches. The wet arc-over distance for each 33 kv pin type insulator is six inches. In figure 2 the suspension insulators are ten inches in diameter, have a distance between centers of $5^3/_4$ inches, and a wet arc-over per unit of approximately four inches. Adding the four inch wet arc-over distance to four times $5^3/_4$ inches (the distance between centers of insulators) gives a total arc-over distance of 27 inches for the five-unit string. This added to the 24 inches of wood on the pole gives a phase to ground insulation length of 51 inches.

Unit of Insulation Strength

For simplicity, it was found desirable to combine the two factors, insulation length and 60 cycle voltage, into a common unit of insulation strength called "inches per kv." This unit is simply the length of insulation in the arc-over path divided by the operating voltage. When determining the phase to phase insulation strength the length of insulation between phases is divided by the line to line voltage, whereas for phase to ground strength the length of insulation between phase and ground is divided by the line to ground voltage. Referring to figure 2, the insulation strength between phases *A* and *B* is 3.1 inches per kv, or 102 inches divided by the line to line voltage, 33 kv. Between phase *A* and the guy it is 2.7 inches per kv, or 51 inches divided by line to ground voltage, 19 kv. For this structure the minimum is 2.7 inches per kv. All comparisons in this investigation were based on the minimum insulation strength of each structure expressed in inches per kv, irrespective of whether it was phase to phase or phase to ground. This was done because experience had shown that phase to phase as well as phase to ground strengths are important in the control of power arc formation.

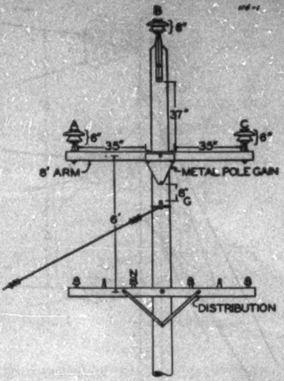

Figure 1. 33 kv high ridge pin structure

	Insulation Length Inches	Insulation Strength Inches Per Kv
A to *B*	84	2.6
A to C	82	2.5
A to G	49	2.6
B to G	51	2.7

Using "inches per kv" as the basis for measurement has the advantage over using lightning flashover data of employing two readily measurable factors, insulation length and 60 cycle voltage, which directly govern the tendency for formation of power arcs following lightning flashover. Taking these factors into account appears to meet in part the need expressed by Andrews[2] in 1938 for data on factors influencing power-follow in addition to lightning flashover data. Factors such as magnitude of short circuit current, circuit tripping time, wind and rain also have some influence, but inclusion of them was beyond the scope of this investigation. There is still need for more study of the influence of all these factors on power arc formation.

It should also be appreciated that the results given here are based on empirical data and that investigations under controlled laboratory conditions with lightning surges superimposed on the 60 cycle voltages would be of considerable value.

Minimum Insulation Level

Having determined the minimum insulation strength in "inches per kv" for each structure from field surveys, the next step was to classify structures according to their strength. The annual rate of trouble experienced in power arc faults per 100 circuit structures was then determined for each group and a susceptibility curve

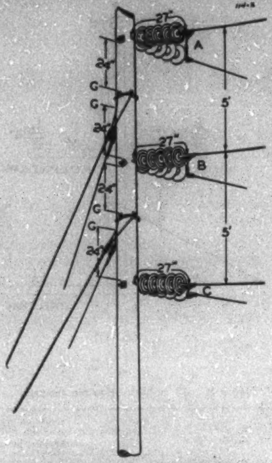

Figure 2. 33 kv corner pole structure

	Insulation Length Inches	Insulation Strength Inches Per Kv
A to *B*	102	3.1
A to G	51	2.7

plotted for each system of the two voltage classes studied. Susceptibility curves based on the composite results for the five year period 1935–39 are shown in figure 3. These indicate that as the insulation strength increases up to a certain level, the rate of power arc faults decreases quite rapidly, whereas further increases beyond this level are much less effective. The fact that the 13 and 33 kv curves do not parallel each other is probably due to the dissimilarity of the two systems in regard to location, number of structures in a given insulation strength class, storm exposure, and other variables referred to in the preceding section of this paper. The significant thing is that both curves show the same general trend and permit selection of a minimum insulation level on which to base construction practice.

Based on susceptibility curves developed earlier in this investigation and similar to those in figure 3, a minimum insulation level of two inches per kv was adopted for the 33 kv system and 3.5 inches per kv for the 13 kv system. These points are just below the knee of the curves. Also, much of the improvement work could be carried on fairly economically up to these levels with substantial reductions in trouble. A level above two inches per kv for 33 kv lines would have been difficult to obtain on many existing structures without replacing the present poles with larger ones. Also, a level above 3.5 inches per kv for 13 kv lines would have required increasing the insulation strength on a large number of low ridge pin poles which were already 3.5 inches per kv, and which had been changed from flat top to this configuration prior to this investigation. The principal aim of the improvement program was to raise the insulation strength of structures which were below the adopted minimum to that value or better. Just how much insulation strength is required for immunity to power arc trouble is not known. However, thus far with 2,300 structure years of experience no trouble has occurred on 13 kv high ridge pin configuration in Philadelphia having a minimum insulation strength of from 6.5 to 7 inches per kv. For the 33 kv system there appears to be no practical value of insulation which will entirely prevent power arc trouble.

Besides being of value in adopting a minimum insulation level the susceptibility curves provide a means for predicting what reduction in power arc faults may be expected by increasing insulation strength from one level to another. Such predictions are of value in determining whether proposed changes on the lines may be economically justified. Being based on five years' experience on a large number of circuit structures, the curves in figure 3 are believed to closely approximate the average annual performance that may be expected for various levels of insulation strength.

In the development of the susceptibility curves power arc faults were selected on the following basis. Any evidence of power arc damage to wires or insulators on a given structure of a single circuit line was classed as a single case of power arc trouble, irrespective of the number of phases involved. Similarly evidence of power arc damage to two circuits on the same structure was classed as two cases of trouble. This classification was necessary because both single and twin circuit structures were included in the analysis. For the same reason it was necessary to place the rate of trouble on a "circuit structure" basis rather than just on a "structure" basis. Thus the number of circuit structures on a single circuit line was taken to equal the number of poles in that line, whereas the number of circuit structures in a twin circuit line was double the number of poles.

Line Improvements

By the close of the 1940 lightning season, the 13 kv line improvement work in Philadelphia had been virtually completed, with approximately 95 per cent of the circuit structures having an insulation strength of 3.5 inches per kv or better. Similarly, improvements to the 33 kv lines had brought about 75 per cent of that system up to two inches per kv or better.

The principal changes on the 13 kv lines consisted of (*a*) removal, relocation or insulation of guys, (*b*) replacement of metal with wood braces, (*c*) use of porcelain or wood sections in the horizontal and vertical operating bars of gang operated air break switches, (*d*) rebuilding of dead-ends and corners, and (*e*) changeover from low ridge pin to high ridge pin configuration by lowering the crossarm or use of wood pole extensions. These changes were made to obtain additional wood insulation between phases and between phase and ground.

As already mentioned, much of the 13 kv construction in Philadelphia had been changed over from flat top to low ridge pin, figure 4, prior to this investigation. However, where pole space permitted lowering the crossarm two to four feet at little cost, this was done to obtain high ridge pin construction. In replacing old poles and in building new lines, the four foot high ridge pin configuration has been used. This construction gives approximately equal insulation strength between phases *A* and *B*, *B* and *C*, and *C* and *A*. It also has about the same dimensions as the 33 kv high ridge pin shown in figure 1 and permits ready conversion to 33 kv operation by merely changing to larger insulators. High ridge pin configuration has been applied to a number of 13 kv pole top switches in Philadelphia.

Changes on the 33 kv system were similar to those cited above. However, much of the improvement to this system has been obtained through relocation or removal of guys and removal of overhead and vertical ground wires. Whatever benefit may have been obtained from the overhead ground wires was nullified by their iron supports and vertical ground leads shunting out the wood pole insulation and thus permitting a ready path for formation of power arcs. Breakage of the overhead ground wires in storms was also another cause for their removal. Pole gains of the type shown in figure 1 have been used extensively to replace metal braces. Isolated groups of steel towers in the wood pole lines at such places as railroad crossings have been improved by replacing metal arms with wood or by adding suspension insulator units up to a total of seven per string. Pole top switches with steel supporting frames and steel operating rods have been particularly susceptible to trouble. Many of these have been rebuilt, using wood supporting members and wood sections in the operating bar. A new design 33 kv vertical switch using post type insulators mounted on two rotating wood uprights is shown in figure 5. This has four feet separation between phases and an insulation strength of two inches per kv. Also on new lines, construction of the type shown in figures 1 and 2 is being used.

Because guys have been one of the chief sources of lightning trouble on both the 13 and 33 kv systems, it is well to consider some of the remedies and certain conditions that should be looked for when trying to obtain additional wood insulation. In most instances improvement has been obtained by lowering or raising guys to the position on the pole which provides the desired amount of wood insulation without sacrificing mechanical strength. Often side guys were found attached to stub poles, which in turn were guyed to ground. Separation of the guys on the stub pole in the manner shown in figure 6 was frequently done to gain wood insulation. This diagram shows an air clearance of nine inches between the guys on the stub so that lightning flashover would be more likely to go across the 15 inches of wood pole rather than across the air gap. If flashover should occur across the air gap, the power arc which followed would therefore be shorter and not so readily interrupted as if flashover had originated across the 15 inches of wood. As a basis for determining desirable air clearance for guys, one inch of air path was taken approximately to equal two inches of wood on an impulse strength basis. Where practical, therefore, an effort was made to have the air gap distance a little greater than half the length of wood insulation.

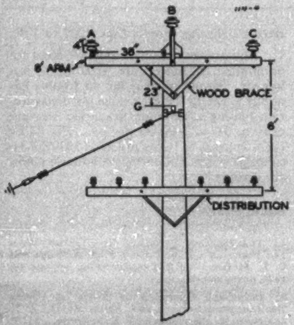

Figure 4. 13 kv low ridge pin structure

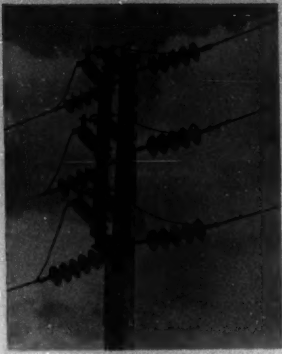

Figure 5. 33 kv vertical switch

Guys were sometimes found too close to line wires, or were brought down at such a sharp angle as to shunt out much of the wood pole insulation by passing too close to a through bolt holding the line suspension insulators as in the case of corner poles. Also, guys which were supposedly insulated from ground were found close to or in contact with lightning arrester ground wires, pipes and conduits on the pole, or to other grounded objects. Tail guys used in dead-ending the three phases of a line were found to converge on a common point of attachment. This condition permitted phase to phase short circuits through the guys when flashover of the dead-end insulators occurred and was remedied by obtaining vertical separation of the three guys on the attachment pole. Where guys could not be effectively relocated, wood guy strain insulators equipped with arcing horns have been used in a number of instances.

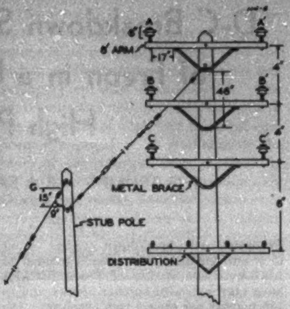

Figure 6. 33 kv twin circuit structure

In this study the conventional porcelain guy insulators were assumed to provide no insulation strength because of their small wet arc-over distance.

Performance

While the susceptibility curves indicate what reduction in rate of trouble can be obtained on individual structures through increases in insulation strength, it is of interest to note what over-all decrease in line interruptions and power arc faults has been obtained through the various changes that have been made.

On the 13 kv system in Philadelphia line interruptions during lightning storms decreased from 55 per 100 circuit miles in 1935 to 14 in 1940, a reduction of 75 per cent. Similarly, 33 kv line interruptions decreased 62 per cent, or from 45 to 17 per 100 circuit miles from 1937 to 1940, in which period almost all of the improvement work was done. While variations in the severity of the lightning seasons affect such comparisons, it is believed that the reductions in line interruptions given above were largely due to the line improvements.

Approximately the same percentage reduction in power arc faults as in line interruptions were obtained. On the 33 kv lines cases of pole splintering without accompanying power arc trouble showed an appreciable increase during the period of line renovation. This was expected and further confirms the results showing the value of increased insulation in reducing power arc trouble.

There has been no apparent increase in

D-C Breakdown Strength of Air and of Freon in a Uniform Field at High Pressures

J. G. TRUMP

R. W. CLOUD
ASSOCIATE AIEE

Synopsis: D-c breakdown studies of air in a uniform field have been extended to 1,000 kv. D-c studies of Freon (CCl_2F_2) have been extended to over 350 kv and to 135 pounds per square inch absolute. The departure from Paschen's law at the higher values of pressure times gap is noted. The mechanisms which account for the higher insulating strength of such gaseous compounds as CCl_2F_2 are outlined and their possibilities and limitations in the insulation of high-voltage apparatus are briefly discussed.

Introduction

IT has long been recognized[1] that the insulating strength of air and other gases in a uniform field increases with the pressure. The classical analysis of the voltage-breakdown mechanism and its dependence on pressure and other properties of the gas was made by Townsend in 1903.[2] This explanation was based on the ionization of the interelectrode gas by both electron and positive-ion collision—a process which Townsend showed would become cumulative when the positive ions produced by the electrons moving toward the anode under the influence of the field become capable, by their ionizing collisions, of producing an even greater number of new electrons. Since that time, Townsend's second coefficient β has been reinterpreted to include various other mechanisms which contribute regeneratively to the charged particles in the interelectrode space. Among these are photoelectric emission, secondary electron emission due to positive-ion impact at the cathode, photo-ionization in the gas, and ionization by excited atoms and by multiple collisions. In addition, it has become evident that any explanation of high-pressure breakdown must also take into account the several processes of ion removal and the important influence of space charge and the myriads of tiny self-healing electron avalanches in modifying the electric field.[3] Recognition of these various ion-producing, ion-removing, and field-modifying mechanisms has clarified the general picture of breakdown in gases but at the same time has shown it to be too intricate for full quantitative description. Because of this complexity, knowledge of gaseous insulation continues to depend to a large extent on the experimental determination of the breakdown strength and pre-breakdown behavior of the various gases as a function of pressure and electrode geometry, and on the investigation—both under simplified and under practical conditions—of the relative importance of the several mechanisms involved in gaseous breakdown. This paper extends d-c breakdown studies in air and in Freon 12 (dichlorodifluoromethane) at high pressures and in a uniform field to higher voltages than have been reported previously, and indicates reasons for the observed departures from Paschen's law and for the relatively high insulating strength of the Freon.

Apparatus

The investigation of the breakdown of air at voltages up to 1,000 kv was made with a pressure-insulated electrostatic generator[4] developed at the Institute for the production of high-voltage X rays for medical use. The uniform gap was established by a fixed electrode of polished steel* attached to the high-voltage terminal and a similar but movable electrode connected to the tank. The diameter of these electrodes was six inches, and their shape was such that in the central gap area the electric field was a maximum and substantially uniform for gaps up to one and one-half inches. The voltage was measured by a generating voltmeter[5] with an estimated error of less than two per cent.

Most of the studies of the breakdown of Freon were made in a 13-inch-diameter

1. For all numbered references, see list at end of paper.

* The several grades of steel, stainless steel, brass, and aluminum give about the same results as electrode materials, the breakdown voltage at higher pressure and gradient being dependent primarily on the smoothness and freedom from contamination of the surfaces rather than on the nature of the metal itself.

---

substation lightning trouble on the 13 and 33 kv systems due to the increase in line insulation.

Summary and Conclusions

1. On the 13 and 33 kv wood pole lines of the Philadelphia Electric Company power arcs following lightning flashover were the principal source of trouble, while lightning itself seldom caused more than slight splintering of the pole or crossarm.

2. The chances of a power arc forming after lightning flashover depend upon the 60 cycle voltage and length of insulation. These factors were combined into a common unit of insulation strength called "inches per kv."

3. Increases in insulation strength up to approximately two inches per kv for 33 kv lines and 3.5 inches per kv for 13 kv lines were found to be much more effective in reducing trouble than increases beyond these limits.

4. These limits were adopted by the Philadelphia Electric Company as a practical minimum of insulation strength on which to base construction practice in renovizing its lines.

5. Improvements to obtain the minimum insulation strength of 3.5 inches per kv or better on the 13 kv system in Philadelphia are believed largely responsible for a 75 per cent reduction in line interruptions during lightning storms from 1935 to 1940.

6. Similar improvements to obtain the minimum insulation strength of two inches per kv or better on the 33 kv system are believed largely responsible for a 62 per cent reduction in line interruptions during lightning storms from 1937 to 1940.

7. The amount of insulation required for immunity to power arc trouble is not known. However, thus far no trouble has occurred on 13 kv high ridge pin configuration having a minimum insulation strength of from 6.5 to 7 inches per kv. For 33 kv there appears to be no practical value of insulation which will entirely eliminate power arc trouble.

steel pressure tank[6] provided with a Textolite high-voltage bushing for 500 kv. External heaters were applied to the tank so that vapor pressures up to 140 pounds per square inch absolute could be maintained. The high-voltage source was a 500-kv constant-potential electrostatic generator of the Van de Graaff type. The voltage was measured with an error of less than three per cent, using a calibrated spiral-line type of high resistance.

Insulating Strength of Compressed Air in a Uniform Field

Figure 1 gives the d-c breakdown voltage of dry air in a uniform field for a range of pressures from 1 to 13 atmospheres and electrode separations up to one and one-half inches. This figure also gives similar data taken in the same apparatus on the breakdown of Freon at pressures up to 45 pounds per square inch absolute, and for voltages up to 500 kv. These Freon data are discussed later in this report. It is to be observed that at each pressure the voltage increases linearly with electrode separation. Since both the voltage and the product of pressure times gap are substantially higher than any heretofore reported, the data on compressed-air insulation are examined with reference to Paschen's law.

It was stated by Paschen[7] and it followed from Townsend's and subsequent analyses that for a given gas and a uniform field the sparking voltage is a function of the product of the interelectrode gap and the gas pressure. The more general similarity law enunciated 50 years later declares the sparking potential of a gas to remain unchanged if the physical dimensions of the electrodes and gap are changed in the inverse ratio to the change in pressure. Paschen's law has been checked at pressures ranging from the critical pressure (corresponding to minimum sparking potential) to many atmospheres, and experimenters have been generally agreed that Paschen's law holds up to gas pressures of ten atmospheres.[8] Some experimenters have measured the linear increase in the breakdown voltage across a uniform gap with gas pressure, and concluded Paschen's law to hold until departure from the linearity was found. It must be pointed out, however, that Paschen's law does not predict this linearity of voltage and pressure, though this linearity does exist over a considerable pressure range. Paschen's law predicts for a uniform field the constancy of the breakdown potential when the product of the interelectrode gap and the gas pressure is constant. In figure 2 the data in figure 1 are replotted to show the variation with pressure of the d-c breakdown voltage across a uniform field in air for constant values of *pd* from 10 to 240 pounds per inch. (One pound per inch = 131 millimeters Hg×centimeter.) It is seen that the relative voltage change with pressure is greater at the higher values of *pd*. The bulk of the recorded data lies in the realm in which Paschen's law fails, so that a slight reduction of voltage with pressure is shown even for the lowest value of *pd*.

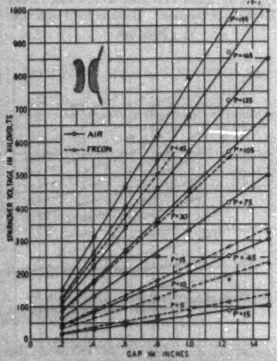

Figure 1. Increase of d-c spark-over voltage of air and of Freon 12 with electrode separation at several absolute pressures in pounds per square inch. Uniform field

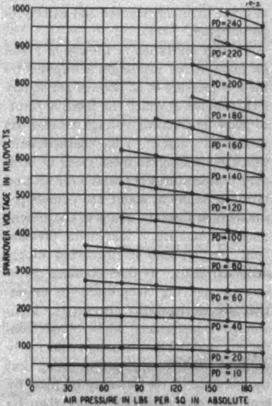

Figure 2. The spark-over voltage in air as a function of pressure for constant values of pressure times gap in pounds per inch

The decrease in the breakdown voltage with increasing pressure at the higher values of *pd* is not unexpected, since the higher gradients favor photoelectric and secondary emission at the cathode. The contribution of the electrode surfaces to the ionization by high field emission may become appreciable at gradients of the order of 10^6 volts per inch, particularly for surfaces that have been inadequately cleaned and conditioned by sparkover or other discharges. Moreover, at higher pressures the reduced mobility and diffusivity of the ions in the interelectrode gap increase the field distortion due to space charge and hence upset the ideal considerations upon which Paschen's law is based. Analysis of other data indicates that departure from Paschen's law begins at values of *pd* of about two pounds per inch. Differences in the experimental values of *pd* at which Paschen's law has been observed to fail are probably due largely to variations in electrode conditioning, which has a marked effect on the breakdown value, as well as to variations in the experimental arrangements such as size, shape, and smoothness of the electrodes, proximity of the chamber walls, and voltage wave shape.

Insulating Strength of Freon at High Pressures

That certain compounds in the gaseous state, notably those which contain chlorine, fluorine, or other electronegative atoms, have a higher insulating strength than air or the other permanent gases, has been known since the investigations of Natterer and others in 1898. A number of studies have been made of the insulating properties of Freon 12[9]—a gas which was developed primarily for use as a refrigerant. As seen from figure 1, Freon can insulate a given d-c voltage at about one-third the pressure required with air. It was felt desirable to extend the breakdown studies of Freon to higher pressures and voltages, since the full advantage of such special compounds over air is realized only if they can be used at essentially the same pressures. Figure 3 shows the breakdown strength of Freon in a uniform field for pressures from 5 to 135 pounds per square inch absolute, and with constant potentials up to 350 kv. Since the vapor pressure of this compound at 70 degrees Fahrenheit is about 85 pounds per square inch absolute, the higher pressures were obtained by heating the chamber the required amount. Care was necessary to prevent condensation of the gas on the electrodes, such condensation lowering the voltages which could otherwise be obtained. A small amount of preliminary sparking was found desirable to condition the electrode surfaces, but the decomposition of the Freon resulting from sparking gradually led to sufficient deposition of carbon on the electrodes to lower the breakdown voltage. This effect was most noticeable at the higher pressures, in which the energy of the discharges was greatest. In general it was found that the behavior of Freon was more erratic the higher the pressure, probably because of the changing nature of the electrode surfaces through carbon deposition and the increasingly high field emission from these surfaces. However, with uniform fields the breakdown gradient continued to increase with pressure, as is shown by the curve in figure 4 for a 0.2-inch gap. Gradients of over 1,200 kv per inch were insulated at 135 pounds per square inch absolute, and there was evidence that with careful electrode conditioning the values indicated by this curve might be increased by about 15 per cent. Figure 5 shows the dependence of the breakdown potential of Freon upon pressure for constant values of pressure times gap. The departure from Paschen's law, as indicated by the slope of these curves, begins when *pd* is greater than two pounds per inch and increases with the higher values. That this departure progresses more rapidly than in the case of air is probably due in part to the influence of inadequately conditioned electrode surfaces.

Reasons for the Higher Insulating Strength of Freon

The higher insulating strength of Freon and similar compounds, as compared with air and other permanent gases, may be ascribed primarily to two causes. The one is the relatively large number of inelastic impacts which an electron may make in such gases[10] with consequent loss of energy and ionizing power; the other is the electron affinity of the electronegative particles in the gas, such as the chlorine and fluorine atoms. This results in the removal of free electrons from the gas with the accompanying formation of relatively inert negative ions. By the former mechanism, such electrons as are created by ionization in the gas are retarded in their accumulation of ionizing energy by the frequent loss of energy on impact. Through the second mechanism the electrons, which are the most effective ionizing agents, are rendered impotent by attachment to heavy electronegative particles.

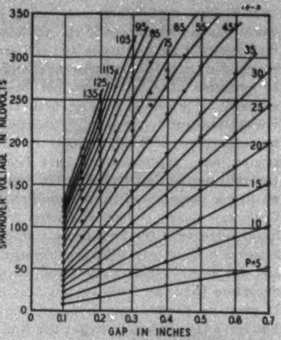

Figure 3. Increase of the d-c spark-over voltage of Freon 12 with electrode separation for absolute pressures from 5 pounds to 135 pounds per square inch. Uniform field

An obstacle to the immediate widespread use of Freon or other such compounds is the gradual decomposition of the gas under the influence of corona and sparkover. In the experimental use of Freon in the pressure-insulated electrostatic generator, although some decomposition of the gas occurred, no impairment of the insulating strength of the gas or of the solid insulation in the chamber, and very little corrosion of the metals was observed after about ten hours. Since there is evidence, however, that the long-time effects of this chemical instability may be serious, this problem and methods of removing the decomposition products of Freon are being studied and will be reported later.

Another limitation to the use of Freon for high-voltage insulation is imposed by the low pressure of 55 pounds per square inch absolute at which the positive point-to-plane breakdown voltage reaches its maximum value.[11] This characteristic, which is common to most gases at ordinary temperatures but which for air and nitrogen occurs at about 160 pounds per square inch absolute, seems at the present time to establish a maximum pressure limit for applications involving highly distorted fields. It thus becomes necessary in applying compressed-gas insulation to electrostatic generators, high-voltage transformers, high-voltage condensers, and the like, to secure sufficiently uniform fields throughout in order that the pressure of the gas may be fixed by economic considerations rather than by an inherent limitation in its insulating properties.

When it is considered that in many high-voltage applications, such as the insulation of electrostatic generators, any increase in the dielectric strength of the gas is reflected (in the limit) as the cube in reduced volume of apparatus, the great practical importance of such superior insulating gases as Freon is realized. It is not unlikely that compounds will become available which show even greater chemical stability than Freon, and at the same time have higher vapor pressures at room temperature. Such gaseous compounds, whose use for insulation is already in a preliminary commercial stage,[12] may ultimately supplant the permanent gases and even liquid dielectrics for the insulation of high-voltage apparatus.

A Five-Figure Table of the Bessel Function $I_n(x)$

HERBERT B. DWIGHT
FELLOW AIEE

THE modified Bessel function of the first kind, $I_n(x)$, where x is a real quantity, is of widespread application, but it is of particular interest to electrical engineers, since the current and voltage for a traveling wave on an electric line can be expressed as a series of these functions.

A table of these functions was published in the Report of the British Association for the Advancement of Science, 1889, pages 29–32, and has been reprinted in "Bessel Functions" by Gray, Mathews, and MacRobert. While a large number of significant figures were given, the arguments were 0.2, 0.4, 0.6, etc.* The interpolation, as used in engineering work, is somewhat easier and more according to a decimal system when arguments 0.1, 0.2, 0.3, etc., are used. Accordingly, additional values for a five-figure table have been computed, and the enlarged five-figure table is given in this paper.

In a number such as $0.0^{8}26053$ in the table, the figure 8 represents the number of zeros before the 2.

The work of computing the new values for this table was done by students under the National Youth Administration at the Massachusetts Institute of Technology, those doing a substantial amount of work including A. L. Carpentier, D. R. Erb, S. Grunes, L. A. King, H. A. Lent, R. P. Mork, R. T. Parry, and B. H. Sexauer.

The values in the table were computed to more decimal places than have been tabulated, and the computations were checked. As a further precaution against errors, columns of differences of the final table were computed and examined for consistency, to a large extent by R. P. Mork, who used the equation

$$\Delta_4 = A - 4B + 6C - 4D + E$$

for the computation of the fourth difference Δ_4 with a calculating machine, where A, B, C, D, and E are any five successive values of $I_n(x)$. This was found to save time and work. See also the introduction to "Tables of the Exponential Function e^x," by WPA of the City of New York, A. N. Lowan, Technical Director. The use of columns of differences is a very searching method of exposing errors in a table.

More than half of the new values were computed by an interpolation method, from the original table mentioned in the second paragraph. Interpolation coefficients given in the paper "Tables and Methods of Extending Tables for Interpolation Without Differences," by George Rutledge and Prescott Crout, *Journal of Mathematics and Physics*, volume 9, 1930, were employed. These, when used with a calculating machine, were found to save considerable work, as no pencil work was needed and no columns of differences of the original table were required. For $x = 5.7$ and 5.9, Gregory-Newton interpolation coefficients were used, and this gave a comparison of the amount of work by the different methods. For the higher orders, the values were proportionately far apart and the power series in x was used, as follows:

$$I_n(x) = \frac{\left(\frac{1}{2}x\right)^n}{n!}\left[1 + \frac{\left(\frac{1}{2}x\right)^2}{1(n+1)} + \frac{\left(\frac{1}{2}x\right)^4}{1\times 2(n+1)(n+2)} + \dots\right]$$

Equations for traveling waves on an electric line, which involve Bessel functions of the type $I_n(x)$, are given on pages 161 and 163 of chapter VII of "Principles of Electric Power Transmission," by L. F. Woodruff, and a numerical example is given on pages 163 to 165.

Acknowledgments are here made for valuable help and suggestions from Professors R. D. Douglass, P. Franklin, and L. F. Woodruff.

The Service Factor Rating of Arc-Welding Generators and Transformers

R. C. FREEMAN
NONMEMBER AIEE

A. U. WELCH
ASSOCIATE AIEE

Synopsis: The primary purpose of rating an electrical machine is to give the user an idea of what he may expect from the unit which he purchases.

It is the purpose of this paper to propose a method of rating arc-welding generators and transformers which will give a truer picture of their working ability than is afforded by the present one-hour rating. Such a method of rating will be beneficial both to the customer who buys and uses arc welders and to the manufacturers who produce and market the units. The user will be better able to select a machine which will do the job to be performed, and at the same time he will be assured that he is not purchasing a machine unduly large for his requirements.

The present custom is to give welding transformers and generators a one-hour rating, specifying the current they can deliver for a one-hour period, starting cold, without exceeding the permissible temperature rise. The plan here proposed is to give them a current rating indicative of their normal operating capacity, or short-time welding ability; and an additional service factor rating, indicative of their continuous current capacity, as limited by thermal considerations.

All electric apparatus has these two major limitations on its output, one a "size" limit expressed by breakdown torque, commutation limit, or voltage drop; and the other a thermal limit expressed by the degrees temperature rise permissible for the type of insulation used. These two limits are usually quite independent of each other, so that no single number, such as a one-hour rating, can fully describe the usability of the apparatus. The proposed service factor rating gives both of these limits, and therefore gives the user the data for applying the apparatus to a variety of duty cycles.

In conclusion, it is suggested that welding generators and transformers be designed for a service-factor rating of 75 per cent, since this corresponds best to typical welding duty cycles. It is also proposed that the standard AIEE values of temperature rise by resistance for continuous rated machines, 60 degrees centigrade for class *A*, or 80 degrees centigrade for class *B* insulation, be recognized as the limiting values in continuous operation at the service-factor rating.

Rating for Welding Service

BEFORE proposing a method of rating, it is advisable to consider the purpose of rating. "The rating of a machine or other equipment is a set of performance characteristics which are subject to verification by test under specified conditions and which by mutual agreement between buyer and seller may serve as a basis of specifications and contracts covering the purchase and sale of the machine or other equipment. The rating is used by the manufacturer in the design and fabrication of the equipment and is used by the purchaser as the basis for application; therefore, the terms in which the rating is stated should be definite, easily verified, of such a nature as to permit intelligent use of the equipment, and as far as possible inclusive of usual conditions as found in practice."[1]

A common sense approach to the problem requires consideration of three different factors:

1. A rating suited to typical welding duty cycles, indicating electrical and thermal limitations.

2. A method of temperature measurement that will give the best indication of actual insulation temperature.

3. Selection of temperature-rise limits to assure satisfactory life of the machine as well as effective use of material in its construction.

In general, there are two types of duty to which an arc-welding generator or transformer may be subjected: Hand welding duty, and automatic welding duty. Because of the infinite variety of hand welding jobs, the duty cycle of such work varies from below 25 per cent up to as high as 75 per cent or 80 per cent of the total elapsed time in the case of production line work. In the case of intermittent welding done in automatic installations, the duty cycles may equal those in the upper brackets of hand welding operation. In a small percentage of cases such as pipe welding and other long seam welding, the length of the arc time may be so long that the application requires a continuous rated machine.

Standards[1] for rating arc-welding transformers and generators now specify temperature rise to be measured by operating the machine at rated current continuously for one hour (one-half hour for the smaller sizes), starting cold. There is also included a statement that transformers should be capable of carrying 75 per cent of rated current continuously. The emphasis has been placed on the one-hour rating and most purchasers, even those having strict specifications of their own, have paid little attention to the continuous capacity, but have required test only at the one-hour rating.

Disadvantages of a Short-Time Rating

In order to illustrate clearly the shortcomings of a short-time rating for machines which must carry cyclic loads, we have borrowed two hydraulic analogy diagrams from L. E. Hildebrand's paper on "Duty Cycles and Motor Rating."[2]

Figures 1 and 2 present hydraulic analogies of temperature rises in two electrical machines. Water flowing into the tank represents motor losses—the smaller stream represents no load losses and the larger stream stands for additional losses under load. The height of water in the tank is analogous to temperature rise, while the capacity of the tank is analogous to the heat storage capacity of the machine. The outlets at the bottom of the tank illustrate heat dissipation.

Paper 41-33, recommended by the AIEE committee on standards and presented at the AIEE winter convention, Philadelphia, Pa., January 27–31, 1941. Manuscript submitted November 22, 1940; made available for preprinting December 7, 1940.

R. C. FREEMAN is in the motor engineering department of the General Electric Company, Lynn, Mass., and A. U. WELCH in the power transformer engineering department, General Electric Company, Pittsfield, Mass.

1. For all numbered references, see list at end of paper.

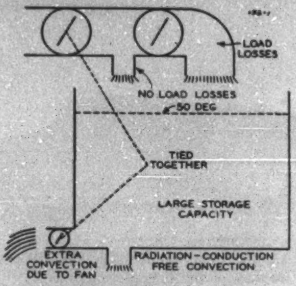

Figure 1. Hydraulic analogy

Short-time rated machines
Poorly ventilated

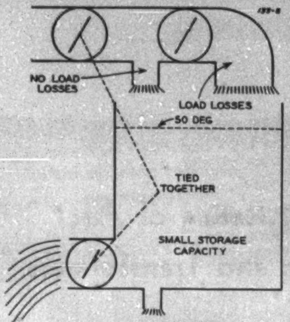

Figure 2. Hydraulic analogy

Short-time rated machines
Well ventilated

In these two diagrams the losses in the two machines are the same. However, in the machine shown in figure 1 we find that the heat dissipating ability as illustrated by the size of the outlet is small, while the thermal capacity of the machine as indicated by the volume of the tank is large; so that in the period of one hour the level of the temperature will just reach a point of 50 degrees rise.

In the case of the diagram in figure 2, we find a machine with a much smaller thermal capacity which is illustrated as a smaller tank. It is only as a result of the large heat dissipating ability as illustrated by the large outlet pipe that this machine is able to run for a period of one hour without exceeding the temperature rise of 50 degrees. Thus, here we have two machines both of which will meet identically the same one-hour load rating specification. But if we were to hold these two machines on a duty-cycle basis all day, we would find a great difference in their operation. The machine represented by the diagram in figure 1 has small heat dissipating ability; therefore, during periods of no load, heat is dissipated from this machine very slowly. During a day's welding, we find that the level of temperature rise continues to climb and may far exceed that obtained on the constant load during the one-hour period.

On the other hand, as soon as the load is removed from the machine represented by the diagram in figure 2, we find that heat is drained rapidly from that machine as a result of the high heat dissipating ability of that unit. With heat being thus quickly and efficiently removed, this unit can run all day on a duty-cycle load and will likely not even reach the level of temperature rise indicated at the end of a one-hour period.

Figure 3 illustrates these points in terms of specific transformer designs. In the figure, curve B_1 is the heating curve of a transformer with a one-hour rating. This same transformer carrying welding load will heat as in curve B_2, if designed with adequate cooling.

However, a transformer could be built with insufficient cooling which would match the one-hour heating curve B_1 but would heat under welding load as in curve B_3. Such a transformer would run considerably over its rated temperature rise on a long-continued load, such as a half a day's work. A transformer designed with heavy copper coils at low current density without adequate ventilating ducts, or a transformer with windings wound close on the core to allow coil heat to be absorbed by the slowly heating core, would meet the one-hour temperature rise but would run hot on actual welding service.

On the other hand, a transformer can be built with heating curves similar to A_1 and A_2. This transformer would reach rated temperature rise in only one-half hour on the short-time test at continuous rated current (curve A_1), but would operate well under rated temperature rise on all-day welding duty as shown by curve A_2. Also, its quick cooling after removal of load (end of curve), would compensate for its quicker heating time by reducing the total time at high temperature.

It can thus be seen that a properly designed transformer rated for a half-hour short-time test may be better than a poorly designed unit which meets the one-hour test. This is the most important reason why a short-time rating may be meaningless. The short-time rating is artificial, does not take into account the important consideration of all-day operation, and does not tell the operator what he can obtain in actual service without injury to the transformer.

Another drawback to the short-time rating is the difficulty of obtaining accurate tests. The problems involved in starting cold, adjusting load accurately and quickly, and timing accurately are serious and make the tested temperature rise obtained doubtful, especially if thermometers are used.

Continuous Ratings

One alternative method of rating is to rate the welding generator or transformer in terms of its maximum continuous current obtainable without exceeding rated temperature rise. This is done to a considerable extent in Europe. Continuous rating suffers from the disadvantage that it does not tell the operator what current he can obtain while welding—always more than the continuous current—since all welding operations are inherently discontinuous loads.

Typical Duty Cycles

In manual welding there is no such thing as a continuous load. In hand welding the maximum time on without interruption is short, about two minutes, the time for one stick of electrode to be consumed. After one electrode is consumed the operator must raise his hood, remove the end of the consumed electrode, insert the new electrode, position the electrode, lower the hood, and restart the arc. This operation consumes time at least equal to ten per cent of the arc time. However, there are always other operations required, such as change or reposition work, chip slag, add parts, change current, rest and delay.

From a careful study of many types of hand welding operations, the writers have come to the following conclusions:

> Many welding duty cycles average about 25 per cent.
>
> On highly repetitive work the duty cycle may rise to about 50 per cent. One such cycle is shown in table I in this paper, and is followed by a similar but simplified cycle, table II, which was used as the basis of a heating test. The curve of temperature rise on this test is shown in figure 4. This particular test was made on a large fan-cooled welding transformer.
>
> Exceptional welding jobs have been found with as high as 72 per cent duty. One such is shown in table III. This shows a time study of a job requiring 63 minutes total. However, there was permitted the welding operator an additional 15 per cent time for rest and delay not shown in the table

which would reduce the duty considerably. It seems probable that 70 per cent approaches the maximum duty cycle which can be obtained in long-continued manual welding.

Other Factors Affecting Heating

Since most arc-welding transformers and generators are furnished in standard ratings and are not built to the exact rating needed for a particular job, the factors of overload and underload should also be considered. The overload range of arc-welding transformers is not very large, generally about 25 per cent. Further overload is prevented by the limit of reactance or other type of current control. Here again proper information on the duty-cycle curve in the hands of the operator would be of value, permitting him to keep within safe temperatures by controlling the duty cycle on those jobs where the overload range is used.

It can safely be expected that in the vast majority of applications the machine will be operated at less than rated current. The range of current obtainable at welding voltages generally goes down to 20 per cent of the rated current in order that one machine may be capable of doing a wide variety of work. In many jobs it is necessary to change current several times to accommodate the different sizes of electrodes required to weld an assembly. However, it is necessary to rate the generator or transformer on a reasonably high duty cycle at its rated current for the rating implies that the equipment may be used for the vast majority of welding operations at that current. Nor is it fair to make the standard duty cycle so low as to deprive the user of any increased life he may obtain when using the machine at less than rated current.

B_3—Average at 60 per cent duty cycle (poorly ventilated)

Suggested Duty-Cycle Standard

When all the above factors are taken into consideration, the authors feel that a standard duty cycle for rating arc-welding generators and transformers should be 60 per cent. A machine thus rated would carry the vast majority of hand welding operations without exceeding rated temperature. Also, since most welding operations do not exceed 50 per cent time on, a reasonable margin is left for operation at some overload. A maximum time on of six minutes out of ten would insure adequate heat storage capacity.

There is precedent for a duty-cycle rating in welding. All resistance-welding transformers are now rated on a duty-cycle basis, the standard being 50 per cent.

The most comparable test would be of course, a duty-cycle test with the generator or transformer continuously excited and alternately loaded for six minutes and open-circuited for four minutes. This test would result in a saw-tooth shaped temperature curve. Such a test is rather difficult to make due to the problem of accurate timing, but it is provided for in the VDE (German) motor standards. Special arrangements might have to be made to test welders where output current is controlled by taps, rather than by adjustable magnetic means, in order to make sure that each winding is properly heated.

Service-Factor Rating

On the assumption that the temperature rise varies as the square of the load current, a duty cycle with 60 per cent time on would give the same heating as a test with $\sqrt{0.60}=0.775$ current continuously. For the sake of simplicity, therefore, it is suggested that the standard temperature-rise test should consist of a continuous heat run at 75 per cent of rated current, carried on until the temperature rise becomes constant. This test will definitely fix the capacity of the machine on a 100 per cent duty cycle, or

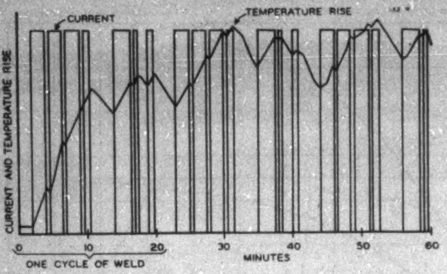

Figure 4. Heating curve

Arc-welding transformer

(51½ per cent welding duty cycle)

continuous service, and it also avoids all the difficulties inherent in making transient temperature measurements. Furthermore, the temperature-rise limit to be prescribed for this continuous test will logically be the same as dictated by experience for all other types of continuous rated apparatus, giving the maximum simplicity in standards.

This 0.75 ratio of permissible continuous output to the rated capacity is called the service factor, as it corresponds to the definition of service factor that has long been used for general-purpose motors. Such motors have 40-degrees-centigrade rise at their rating, and a service factor of 1.15, corresponding on the average to the increased load at the 50-degrees-centigrade rise value permissible for continuous rated apparatus in specific applications.[3]

It has already been suggested by L. E. Hildebrand that service factor ratings of less than unity should be used for high torque motors on intermittent duty cycles, instead of the customary short-time ratings.[2] The same reasoning outlined in the preceding paragraphs applies to a wide variety of apparatus in intermittent use. In each case the nameplate rating should be indicative of the safe allowable load for a particular kind of duty, and the service factor indicates the permissible continuous, or rms, load.

On the several grounds of convenience, testing accuracy, and versatility of application, therefore, the service-factor rating method is suggested as preferable for welding transformers and generators; and the specific value of 75 per cent service factor is suggested as most suitable for usual arc-welding service.

Automatic Welding

All the foregoing discussion refers to hand welding, that is, welding with the electrode holder in a man's hand. No attempt will be made in this paper to recommend duty-cycle ratings for automatic machine welding. Many machine welding installations operate at very low duty cycles since it often takes longer to load and align the work in the machine than to make the weld. Many other installations, particularly where one transformer is switched alternately between two welding machines, one welding while the other is loading, operate at very high duty cycles, on the order of 80 per cent or higher. Fortunately, it is not so important to have a standard for such installations since they usually represent such large investments as to justify individual study and application.

Temperature-Rise Measurement

The aim of temperature-rise measurement is to determine the hottest temperature reached by the insulation, in order that long life of the machine may be assured.

The three general methods of temperature measurement are: The measurement of the temperatures upon external parts of windings or core by thermometer or thermocouple, measurement from the cold to hot resistance change of a winding, or the use of embedded detectors.

As a result of the demands of the industry for easily portable arc-welding sets, the trend of generator designs is to small machines which are very well ventilated. The fact that these units are so well ventilated by an air blast means that there is, of necessity, a greater thermal gradient from the inside of the coil winding to the external surface of the insulation. This means that surface temperatures vary widely from internal temperatures and that the extent of this variation is influenced considerably by the method of ventilation employed.

It is very difficult to get accurate transformer temperatures by thermometer or thermocouple unless thermocouples are actually built into the winding. In most natural draft transformers, particularly those with heavy coils, a thermometer or thermocouple on the outside of the coil may read 20 to 30 per cent lower than the average temperature rise of the winding. The rise by resistance method, of course, becomes mandatory in oil or synthetic fluid-immersed transformers since it is then practically impossible to insert thermometers or thermocouples.

While the embedded detector method is of unquestioned desirability in heat flow tests, its use in commercial testing is pretty much out of the question.

A combination of the inadequacy of surface temperature measurements with the difficulty of making embedded detector measurements leads us to the measurement of temperature rise by the resistance method. By the resistance method, it is possible to obtain a true average winding temperature regardless of whether the coil is exposed to a blast of cooling air or whether it is well wrapped up in electrical and thermal insulating material. Although this method will, of course, not give an actual hot-spot temperature indication, yet it will be a much more reliable indication of the hot-spot temperature than any surface temperature measurement.[4]

As an aid in attaining a true indication of temperature rise, we will find that the adoption of the duty-cycle or service-factor method of rating is of considerable help. With short-time periods of test the rate of rise of internal temperatures may be so great that measurements of a final surface temperature are likely to be very inconsistent and consequently therefore, also inaccurate. While it is a fact that a true sportsman will not shoot at a standing bird, fortunately there is no sporting or ethical principle which requires the builders of arc-welding equipment to attempt to measure temperature rise "on the wing." With the adoption of the service-factor method of rating welders it will be possible to allow the temperature of the machine to reach a state of equilibrium and thus allow accurate measurement. The combination of service-factor rating with temperature rise by resistance measurement will assure us that we do not have our heads in the sand but that we will actually know the average temperature rise of the windings in our arc-welding machines. To know the true values of temperature rise is of unquestioned advantage for both the user and the manufacturer of welding machines. The manufacturer can know that he is making optimum use of all of the material within the machine without exceeding safe temperature limits; while the purchaser will be assured of long life machines giving trouble-free operation.

Limiting Temperature Rise

The two important factors governing the life of insulation are maximum temperature and the length of time the insulation is hot.

The maximum permissible operating temperature of the insulation is a function of the type of insulation, both fibrous materials and impregnating compounds. The general subject of insulation characteristics is too long to discuss here, so for the purpose of this paper it will be assumed that the commonly accepted standards[4] will insure satisfactory life of insulation, and that these rises should not be exceeded except for very short intervals of time.

For a given temperature, the life of insulation is reduced more or less directly with time; that is, if a transformer were hot only one-fifth of the time, its insulation could be expected to last five times as long as one hot continuously. For class *A* insulation it has been shown[5] that within limits the life of insulation is reduced roughly 50 per cent for each 8- to 12-degree increase in temperature. Therefore, the life reduction, in aging units, can be approximately estimated in the form of an exponential function of temperature, multiplied by the length of time the temperature persists in the insulation. For class *B* insulation, such as is used in most arc-welding transformers, the rate of aging has not yet been determined; however, it undoubtedly follows some similar law but probably with a higher temperature increment for a given aging.[6]

From the foregoing factors it will be seen that the shapes of the heating and cooling curves of a welder affect insulation life. For example, a welder which heats slowly may have the advantage of slow heating offset by cooling more slowly and thereby keeping its insulation hot longer than a welder which heats and cools quickly.

Since the present NEMA standards for welding generators require measurement of temperature rise by thermometer, it is pertinent to inquire what the corresponding values of rise by resistance are for actual machines now in use. As pointed out previously, and recognized in the AIEE "General Principles Upon Which Temperature Limits Are Based in the Rating of Electrical Machinery and Apparatus," there is a considerably greater difference between the two methods of measurement for highly rated direct-current machines than the ten-degree-centigrade value usually assumed for class *A* insulation. With the forced draft ventilation commonly in use on arc-welder sets, the thermal gradient between the inside windings and the outside of the coils is so great that the actual excess of the rise by resistance over that by thermometer is often 20 degrees centigrade or more.

Depending upon the thickness of insulation over the windings and the intensity of the blast of ventilating air, it is a matter of test record that temperatures measured by the resistance method range from 17 to 42 degrees higher than the values read by thermometer or thermocouple at the outer surface of the coils.

In view of the intermittent character of hand welding, and the satisfactory service records of welders having these relatively high internal temperatures under rated load conditions, it is permissible to set considerably higher limits for temperature rise for short-time rated than for continuous-rated machines. For example, the latest NEMA welding standards[1] permit 100-degrees-centigrade rise by thermometer, or 125 degrees centigrade by resistance, for "class *BB*" insulated welders rated on a half-hour or one-hour basis. Presumably this insulation is similar to the special class *B* insulation used in railway motors, for which 120-degrees-centigrade rise by resistance is permitted.[7] However, as previously indicated, the typical welding duty cycle of 60 per cent time on and 40 per cent time off with a time cycle of only a few minutes, results in no greater operating temperature than would be caused by a continuous load of about 75 per cent of the short-time rated amperes. And, to assure the service life normally expected of electrical apparatus, this average operating temperature should not exceed the standard limiting values for continuous-rated machines, which are: For class *A* insulation, 50 degrees centigrade by thermometer or 60 degrees centigrade by resistance, and for class *B* insulation, 70 degrees centigrade by thermometer or 80 degrees centigrade by resistance.[12] Thus, the 75 per cent service-factor rating method with the standard continuous-temperature limits is a logica outcome of the recent trends in welding transformers and generators.

Table III. Typical Heavy Duty Cycles—Hand Welding

Minutes on	Minutes off	Minutes on	Minutes off	Minutes on	Minutes off
	2.07	1.24	1.72	0.66	2.92

1.54	0.19	0.90	0.19	0.34	0.19
1.54	0.19	0.90	0.19	0.34	0.60
1.54	0.19	1.24	0.85	2.37	0.44
1.54	0.19	0.66	0.19	2.37	0.18
1.54	0.70	0.66	0.19		
1.24	0.19	0.66	0.19		
Total				45.88	17.26
Duty cycle				72.7%	

Conclusions

After consideration of all these factors, it is recommended that welding generators and transformers be given a nameplate rating representative of their expected normal welding currents, as at present, and in addition a service-factor rating of 75 per cent. Acceptance tests would then include a continuous test run at 0.75 of the nameplate amperes without exceeding a limiting temperature rise by resistance of 60 degrees centigrade for class *A* insulation or 80 degrees centigrade for class *B* insulation; or corresponding values of 50-degrees-centigrade and 70-degrees-centigrade rise if the thermometer method of measurement is used.

Engineering Requirements for Program Transmission Circuits

F. A. COWAN

I. E. LATTIMER
MEMBER AIEE

Synopsis: Present-day program networks are reviewed from the standpoints of engineering, design, and operation as developed to meet the needs of the broadcasters. The factors requiring consideration in the further development of program networks in anticipation of future needs are also discussed. The presentation of the paper is supplemented by a demonstration of the quality obtainable by transmission over various types of telephone facilities.

Introduction

THE growth of radiobroadcasting to the magnitude of a major national industry within the last 20 years has been accompanied by the development of a nation-wide system of wire-line networks interconnecting hundreds of broadcasting stations. Papers have been presented before this Institute from time to time[1,2,3] describing the types of plant used for these networks and discussing important features of their design and operation. With these 20 years of experience as a background, it should now be of interest to review how the various requirements of broadcasting have influenced the development of the networks and to consider some of the factors which have determined the point to which transmission and operating features have so far been carried.

Simply stated, broadcasting is a means by which sounds originated at one place are reproduced simultaneously to large numbers of listeners distributed over wide areas. The simplest possible radiobroadcasting system would consist of a microphone, a radiobroadcast transmitter and some radio receiving sets. Such a system could serve only the listeners within the comparatively limited service area of the transmitter. To serve the whole nation many transmitters must be established about the country. Furthermore the most desirable sources of program are not usually in the neighborhood of the transmitter to which a particular listener can tune, since talent tends to be concentrated in certain parts of the country, and special events of interest may occur anywhere. To give a true country-wide service so that every listener can hear the programs he enjoys wherever they may originate, a supplementary transmission system must be provided, interconnecting the many studios and broadcasting stations. The wire networks that perform this function comprise the subject matter of this paper.

The present extent of the wire-line facilities which are associated with the major portion of these networks is indicated in figure 1. The width of the lines on this chart has been made proportional to the numbers of circuits in the various sections. The total length of these circuits is in excess of 110,000 miles, and it is not unusual for a program originating at some point on a network to traverse more than 7,000 miles of circuit before being broadcast by the most remote station.

The requirements which the program networks must meet are in the final analysis determined largely by the needs of the broadcasters. The objective of a program network service is to meet these needs in as complete and prompt a manner as possible consistent with reasonable cost. With this objective in mind, it is necessary in planning the plant to consider not only the day-to-day needs, but the possible future needs as well. The importance of this may be appreciated when it is considered that plant provided today for program transmission service will need to be adaptable to the service requirements 10 or 20 years hence. As a result of such planning, cables and equipment installed 5, 10, and 15 years ago, meet present-day requirements, and with some rearrangements, will take care of those likely to develop tomorrow.

The detailed planning of program transmission circuits requires consideration of:

1. The numbers of circuits likely to be required, section by section, over each route;
2. The provisions for reliability, flexibility, operation, and supervision essential to a high-grade network service;
3. The transmission requirements, or electrical characteristics, necessary to achieve a natural reproduction of the program.

These three general classes of requirements will be considered in order.

Number of Circuits Required

The circuits which have been established on a full-time basis for continuing use form the backbone of the program networks. Even for these circuits, however, permanence is relative since frequent extensions and rearrangements are made to meet changing requirements of the broadcasters. Aside from these full-time circuits there are intermittent requirements occasioned by special events and other short-period needs of the broadcasters, some of which involve networks almost as extensive as the full-time networks. In addition reliability of service requires provision for rerouting the networks in the event of trouble. Figure 2 shows the year-by-year growth in the operated mileage of program circuits for the period 1926 to 1940. Of the more than 110,000 miles of circuits shown for 1940, about 45,000 miles have been provided for the short-period services and as stand-by facilities for protection. In addition to these, there are still other circuits, normally assigned to other services, which are arranged to be readily adaptable to program service to supplement the reserve facilities maintained on a full-time basis.

The time interval necessarily accompanying any extensive construction project makes it necessary to engineer plant considerably in advance of actual service requirements to meet, not only the expected growth, but also the changes in network routing. Figure 3 shows for two typical sections along major routes the variations in requirements for full-time network circuits resulting from growth and rearrangements required by the broadcasters. While, in planning to meet these rapid variations in circuit requirements, advantage can be taken of some latitude which exists in the choice of routes for occasional services and protection facilities, the task of balancing the provision of circuits against requirements is an entertaining and at times difficult one for the circuit engineer.

Operating Requirements

Considering for a moment the variety of programs originating at many different

Figure 1. Major network circuits in the United States

points that can be heard on any home radio set in the course of an evening without once changing the tuning, it will be apparent that minute-to-minute rearrangements of an established interconnecting network must be possible. For example, studios have to be changed from receiving to originating, sections of the network have to be made to transmit first in one direction and then in the other, and branches have to be connected and disconnected. These changes in the network have to be made in the few seconds elapsing between the close of one program and the start of the next on the receipt of selected cue words or sounds. Even during the course of a single program, switches or reversals may have to be made to change the originating point temporarily. To provide for these rapid changes, special operation and special switching and reversing equipment are required at many points along the network. Much of this equipment is under remote control from selected points.

The greater portion of the switching of program circuits is done at about 25 points throughout the country on the major networks. On the average more than 25,000 switching operations per month are performed at these 25 points. During the busy hours of any typical evening there may be something over 500 men on duty at all of the offices about the networks.

At points where switching requirements are simple, the switching equipment consists merely of a few keys. At the larger points where the switching requirements are complex, the switching equipment consists of elaborate relay and control arrangements. These are so designed that it is possible to set up in advance the circuit combinations required for the ensuing program period without disturbing the programs in progress. The actual switching operation takes place at the instant the monitoring attendants signal the receipt of the last of selected cues, and not before then. This type of arrangement affords a maximum of protection against error, as it is possible to check the presetting for the next switch or make a last minute change if necessary any time before the switch has been made.

Figure 4 shows a picture of such a switching arrangement in use at Omaha, Nebraska for one broadcasting company.

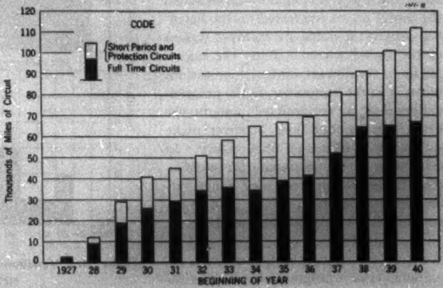

Figure 2. Growth in mileage of major network circuits

At this point 13 circuits used in various trunk and branch sections of two networks are connected to the switching equipment. These are grouped in various combinations to take care of as many as five simultaneous programs. A maximum of five cues might, therefore, be involved in a switch at this point.

The operation and maintenance of the networks are carried out by a special organization under centralized authority and trained in the application of uniform methods and procedures found by experience to be productive of best results. Transmission is monitored continuously at strategic points about the networks. In order to facilitate the activities of this group many thousands of miles of intercommunicating telephone and telegraph circuits are provided full time for their use.

A picture of a monitoring position in the program transmission office at Washington, D. C. is shown in figure 5. It will be noted that the monitoring attendant is using an individual headset. This is of a special high fidelity type and is used to avoid the confusion that would result from attempting to monitor a number of different programs simultaneously with loud-speakers. Loud-speakers are available, however, for supplementary checks of quality whenever required.

Accurate transmission measuring equipment is necessary at the various operating points about the networks to insure satisfactory transmission maintenance results.

Transmission Requirements

The general transmission requirement for a broadcasting system is that the program material be transmitted with a high degree of naturalness. Although the exact determination of the transmission characteristics which would accomplish this involves many considerations it will be assumed in this discussion that an ideal transmission system is one in which the sound waves impressed on the listeners' ears in the home are an exact replica of the sound waves striking the microphone in the distant studio. Limitations inherent in the human ear, in the program material to be transmitted, and in the usual listening conditions, however, make such ideal transmission unnecessary. In expressing the requirements for satisfactory transmission, frequency range, attenuation distortion, delay distortion, nonlinearity and noise are used as indices of quality.

Before taking up the transmission requirements of a program circuit, it is important to consider further the fundamental factors that are involved in fixing the characteristics considered desirable for the entire system. According to Harvey Fletcher,[4] the zone of audibility of the average normal human ear for pure or single frequency sounds is the area within the curve of figure 6. The abscissas represent frequency and the ordinates show the range of intensity recognizable as sound, between the lower limit or threshold of audibility and the upper limit where the sensation of pain is felt. It is seen that the extreme frequency range shown on the chart is from about 20 to 20,000 cycles per second. This range is for young people. It is considerably less for middle-aged and elderly people, and varies with individuals.

In addition to the limitation of the ear there is the fact that there is little energy present in most program material in the extremes of this range, particularly in the upper frequencies. The energy versus frequency spectra of music and other forms of program have been published elsewhere.[5] Figure 7 shows the frequency range which must be transmitted for a number of instruments, speech, and certain noises, so that competent observers cannot detect any impairment.[6] For whole orchestras, experiment has shown that the elimination of frequencies below 40 and above 15,000 cycles per second is undetectable.[4] If the upper limit of the transmitted frequencies is lowered from 15,000 cycles, the impairment is at first barely detectable but increases at an accelerating rate. When the limit is materially lower than 8,000 cycles, the loss is readily apparent to many people.

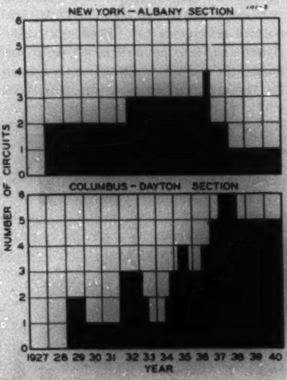

Figure 3. Variations in full-time program circuits

Figure 4. Switching panel at Omaha, Nebraska

Another important consideration is volume range—that is the difference between the maximum and minimum levels of the program. The ordinates of figure 6 show that for part of the frequency range, the ear can respond to a range of intensities of more than 120 decibels, with perhaps 100 decibels as a mean. However, the following considerations show that the volume range which the transmission system needs to accommodate is considerably narrower than the intensity range to which the ear can respond.

In the first place, the range of program volumes to which the ear can respond is much less than the range of single-frequency intensities shown by the curve. Program waves are in general very irregular in shape, and even at constant volume contain large and small peaks differing in amplitude by many decibels. The range between the volume at which the highest peaks reach the maximum instantaneous intensity which the ear can tolerate and the volume at which the smallest peaks are just above the threshold of audibility is therefore less by a number of decibels than the intensity range of the ear as measured by single frequencies.

In the second place, the volume range of the usual program material has definite limits. Measurements have shown that a large symphony orchestra produces a maximum volume range of about 70 decibels.[4] The volume range of most other types of program is considerably less than this, for example, being only about 25 to 30 decibles for dance music and as little as about 15 decibels for much of the dialogue of actors in radio drama.

In the third place, the usual listening

Figure 5. Monitoring position at Washington, D. C.

conditions impose a definite limit on the useful volume range. The loudest passages in the music of a symphony orchestra correspond to a sound level of about +95 decibels at a point, say one-third the way back in an auditorium, but most people in their homes prefer a level which is lower than this by 5 to 10 decibels. Figure 8 shows the results of an extensive survey[7] of acoustic room noise in homes. It will be noted that the average noise level is +43 decibels on the sound-level scale, and that few homes are quieter than +30 decibels even in the suburbs. The signal-to-noise range inherent in the listening conditions, and allowing nothing for the noise contributed by the transmission system or the room noise where the program is being produced, is therefore seen to be somewhere between 45 and 65 decibels. There is therefore, no advantage to the listener in providing a permissible volume range materially wider than this in the transmission system.

The above discussion applies primarily to the transmission of symphonic and similar high-grade program material. Much program material is less exacting in its requirements, but on the other hand some sound effects such as the tearing of paper require the reproduction of higher frequencies for complete naturalness.

With these broad considerations in mind, the requirements of high-quality program circuits may now be taken up. As has been noted, the program network is but one part of the over-all broadcasting system which, in addition, includes microphones and studio equipment, radio transmitters, and the home receivers with their loud-speakers. It may be taken as a goal for the program networks that their transmission be nearly enough distortionless so that the over-all performance in regard to naturalness of reproduction will not be limited by them.

To meet such a requirement for short program circuits having only one or two sections is not difficult technically, and does not in general require costly types of plant. However, the vast country-wide program networks are made up of many sections of circuits in tandem, which as mentioned before may total in some cases as much as 7,000 miles. This makes it necessary to design and operate the individual circuits to very close limits so that the cumulative discrepancies in the whole network will not exceed tolerable values; and to consider carefully the types of plant employed lest by virtue of sheer numbers of units involved, the total cost be out of line with the over-all grade of service being given the listener. These two conflicting factors are important ones in the consideration of transmission requirements for networks. The determination of the practical working characteristics of program networks involves a consideration not only of the physical and cost factors discussed above but also of such other factors as cost of studios, broadcast transmitters and receivers, and the limitations of the frequency allocations of broadcast stations.

From the standpoint of frequency band the consideration of all factors has resulted in the major present-day program networks being set up to transmit a frequency band with an upper limit of about 5,000 cycles. All program facilities installed in the last ten years or so, however, have been designed to be adaptable to the future transmission of frequencies up to 8,000 cycles. Operation on an 8,000-cycle basis, however, requires the release of additional frequency space now occupied by other services in much of the plant and a general readjustment of the program-circuit characteristics. In 1933, experimental wire circuits were set up between Philadelphia and Washington to transmit frequency bands up to 15,000 cycles. These were employed in a demonstration of stereophonic transmission and reproduction of music.[4] Studio-transmitter loops have been provided to transmit wider frequency bands than the 5,000 cycles currently provided on the nation-wide networks. At the present time, many of the studio-transmitter loops are being set up to transmit bands up to 15,000 cycles. A demonstration will be given at the close of the paper of the transmission of programs over cable circuits about 1,200 miles in length with frequency bands extending to 15,000, 8,000, and 5,000 cycles. The 5,000-cycle circuit is of the type in present commercial use. The 8,000-cycle circuit is of a type to which much of the present program plant can readily be modified. The 15,000-cycle circuit consists of a standard carrier system to which has been added program terminal equipment now under development.

In the consideration of transmission requirements for program circuits other than nominal frequency band, the varia-

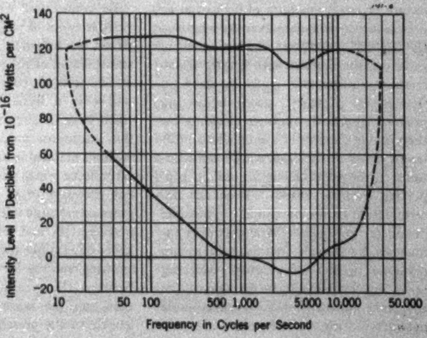

Figure 6. Limits of audible sound

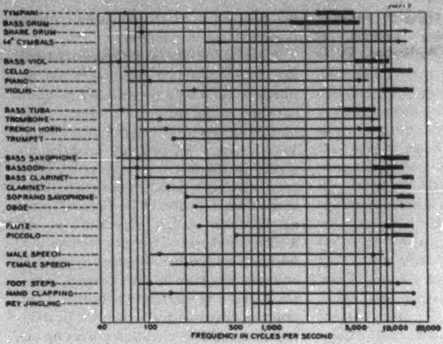

Figure 7. Audible frequency ranges of music, speech, and noise

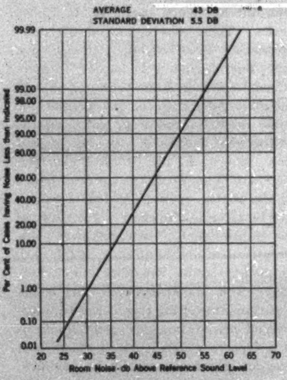

Figure 8. Residence room noise with radio sets silent

tion in performance with length and type of circuit is important, since the factors tending to impair transmission are in the nature of small amounts of distortion or noise which accumulate over the length of the circuit. If these effects varied in some definite manner with length, transmission requirements could be fixed on that basis. However, good engineering practice frequently requires choosing for the various sections of a long circuit, different types of facilities whose contributions to the total effects are not in proportion to their length. Even the determination of the maximum permissible distortion and noise on a circuit is influenced by outside factors such as are involved in the broadcasters weighing operating flexibility and cost against the frequency of occurrence of unfavorable network routings and the number of stations affected. For example, in order to secure operating flexibility with a minimum of total network mileage, most of the networks employ the so-called "round robin" principle for a part of the network. In this arrangement the circuit follows a route from station to station forming a continuous loop which returns to its starting point. This naturally results in increased circuit mileage between the program source and the more distant listeners with an attendant increase in undesired transmission effects. For these reasons no exact or specific transmission requirements can be stated for even the over-all performance of program transmission service.

Volume Range

The permissible volume range for a program circuit is determined by the maximum volume which can be transmitted as limited by nonlinear distortion or cross talk, and the minimum volume which can be transmitted without impairment from the noise present on the circuit.

In connection with their design the various types of program circuit are subjected to listening tests in which the transmission of program over a long loop of the circuit is compared with transmission over a local distortionless circuit. Each type of circuit thus is rated as to the maximum volume it can transmit without noticeable distortion. The highest volume which can be permitted without excessive cross talk into other program or message telephone circuits is also investigated, and whichever limit is the lower determines the maximum allowable working volume for service. The range between the maximum permissible volume and the noise level on very long lengths of the present program circuits is about 45 or 50 decibels, except under some conditions on certain open-wire sections. On the individual links making up the long circuit, the range is 10 or 20 decibels greater than this.

Attenuation and Delay Distortion

Another important consideration is the amount of attenuation and delay (or phase) distortion to be permitted within the transmitted frequency band. It is the practice to equip program circuits with adjustable attentuation equalizers. By means of these once the desired frequency band has been chosen the deviation in attenuation at any frequency within that band, compared with that at 1,000 cycles, can be adjusted within close limits. On very long circuits, however, experience has shown that even with automatic regulating features and careful operation residual variations which may amount to several decibels may develop as a result of changing temperature and other conditions. These variations are kept within tolerable limits by readjustment of the equalizers from time to time.

Associated with the attenuation distortion is another effect detrimental to program quality, namely, differences in time of transmission for different frequency components of the signal. In practice circuits tend to have a lower velocity of transmission near the edges of the frequency band than in the middle portions. This results in frequency components near the edges being delayed as compared to the middle portions of the band. This difference in time of transmission is called delay distortion of the circuit. Careful listening tests have shown that it becomes noticeable if, at the highest transmitted frequency, the delay is more than eight milliseconds greater than at 1,000 cycles, and if, at 100 cycles, it is more than about 15 milliseconds greater than at 1,000 cycles. It is controlled by careful attention to the design of loading systems, amplifiers, repeating coils, and all other elements of the circuit. Since such small amounts of over-all delay distortion are detectable and since networks frequently have 100 or more amplifiers in tandem between an originating point and the broadcasting stations on the more distant portions of the networks, it is necessary that the delay distortion of all individual components of a network be held to exceedingly close limits. Accumulations of residual delay distortion which cannot be entirely eliminated in design are reduced by the use of delay equalizers along the circuits when they are set up.

Prime-Mover Speed Governors for Interconnected Systems

R. J. CAUGHEY
NONMEMBER AIEE

J. B. McCLURE
ASSOCIATE AIEE

Synopsis: System operating requirements, from the standpoint of frequency and tie-line loading, are continually becoming more rigorous and receiving more widespread attention. Supplementary controls have been developed to assist in the solution of these problems—but the speed governors of the prime movers still constitute the backbone of system control.

This paper outlines the general problems encountered; gives definitions of terms for both steam and hydro governors and discusses the performance characteristics of these two general classes of prime movers. As a result of discussions with several operating groups certain definite conclusions were reached for prime-mover governor characteristics on the larger systems, viz., dead band should be as small as practicable; uniform incremental regulation desirable; adjustable regulation not necessary; similar rates of response not necessary and accurate response to supplementary control desirable. These conclusions are supported by the analytical work presented in the companion paper.[1]

A summary of the reasoning supporting these conclusions under the subjects of stability, dead band, regulation, response, short circuits, and tie-line swings is included.

Introduction

DURING the past several years the interconnected power system has come into being and has expanded rapidly to the point where some of these systems now comprise several million kilovolt-amperes of connected capacity. Many problems have appeared and of these, two important and closely associated ones, speed and load control, have continued to receive increased attention. In most cases large portions of these systems are tied together by tie lines of relatively small capacity and as a result power flow across the ties must be carefully controlled.

Frequency control is being widely used in varying degrees of refinement and automatic tie-line control is being used in more and more locations.[1,12,13,14] The control associated with these two problems is usually applied in the form of relatively slow supplementary adjustments to the normal action of the basic speed governors, which still constitute the backbone of system control. It is logical, then, as system operation becomes more refined and the requirements more rigorous, that more attention[2,3,4] be given to the characteristics of the speed governing mechanisms. During this same period special instruments[8,9,10] for accurately measuring small changes in system frequency have been developed and these instruments have been used to advantage by several groups in analyzing governor performance.

The manufacturers of power generating equipment endeavor to equip their prime movers with suitable governing equipment.[5,6] Also, in the analysis of power system performance it is essential to appreciate the influence of all associated apparatus, including speed governors[11,15] on system performance. On this basis, the general problems associated with speed governing were discussed with several operating groups, and with the evidence procured so far, we have reached certain definite conclusions as to what characteristics prime mover governors should have to meet the operating requirements on the larger power systems.

Definition of Terms

There is a surprising lack of a common language for this subject and thus, before proceeding further a brief definition of terminology used *in this paper* will be in order. Two sections in the ASME—Power Test Codes for Governors and Committee on Industrial Instruments and Regulators—each have a set of definitions and this is no attempt to

---

Paper 41-24, recommended by the AIEE committee on power generation, and presented at the AIEE winter convention, Philadelphia, Pa., January 27–31, 1941. Manuscript submitted November 27, 1940; made available for preprinting December 3, 1940.

R. J. Caughey and J. B. McClure are with the General Electric Company, Schenectady, N. Y., Mr. Caughey in the turbine engineering department and Mr. McClure in the central station engineering department. J. B. McClure and R. J. Caughey are members of The American Society of Mechanical Engineers.

The authors wish to express appreciation to the representatives of the operating companies who contributed during the several discussions on this subject and to acknowledge the assistance of Messrs. C. Concordia, S. B. Crary, and E. E. Parker of the General Electric Company in the preparation of this paper.

Conclusion

From this discussion it is seen that the program networks are comprised of many parts, each of which must meet exacting requirements in order that over-all results will be satisfactory. It is seen that equally important with transmission are the requirements for plant flexibility, adequate reserves, uniform practices, and centralized supervision of the networks.

The features discussed have been those found desirable for present-day network service. As indicated earlier, consideration of the needs of the future as well as those of the present is an essential feature of the design and engineering of the plant for program-network service. As a result of having done this it will be possible to provide with present plant, and with new plant currently being installed, adequate network facilities as the broadcasting art develops toward higher standards of performance. With the past experience as a guide, it appears that there should be no fundamental difficulty in meeting all reasonable requirements, always remembering that in the long run, requirements and costs bear definite relations to each other.

arbitrate any differences, or establish new terms. A final decision on terminology will be reached through mutual agreement between representatives of manufacturers and operating groups both in the AIEE and ASME as well as other contributing groups.

Speed governor shall include the speed responsive element which positions a member in terms of speed. In figure 1 this is schematically represented by a conventional spring-restrained centrifugal flyball mechanism, but an oil pump working against a spring loaded diaphragm or a resonant circuit producing a torque motor effect will perform the same function.

Control mechanism shall include all linkages, pilot valves, dashpots, operating cylinders, cam shaft, cams and valves necessary to control the prime mover input in terms of speed governor position. In figure 1 a single pilot valve is shown between the speed governor and the operating cylinder. As the required pilot-valve size increases, a larger and more powerful speed governor is required. Instead of this, a relay mechanism or amplifier consisting of an intermediate pilot valve and piston is often interposed between the speed governor and the main pilot valve.

Governing mechanism shall include both the speed governor and control mechanism all as shown schematically in figure 1.

Over-all regulation is the sustained per cent change in speed of a prime mover for full load change from an initial speed of 100 per cent.

The regulation of the mechanism shown in figure 1 may be changed by varying the ratio of linkages, but there is always a lower limit for regulation below which stable operation cannot be obtained. This limit is determined by system conditions as well as by governor mechanism characteristics—but other conditions being similar, faster mechanisms permit smaller regulation with stability.*

Operating piston times for steam units are in the order of one second or less—whereas servo-motor times in hydro units are four seconds or greater to satisfy hydraulic conditions. Thus, if this simple mechanism in figure 1 were employed in a hydro governor, the regulation required for stability would be so large that other operating requirements would not be satisfied.

The manufacturers of hydro governors have solved this problem very neatly by employing droop correction as shown in figure 2. For sudden changes the dashpot acts as a rigid connection—giving broad transient regulation for stability, but after some time delay, the action of the dashpot and springs produces a much smaller steady-state regulation. In the figure, zero steady-state regulation is shown, but for paralleling purposes, the necessary amount of over-all steady-state regulation is obtained by positioning the spring supports in terms of operating cylinder position. Thus, droop (the remaining droop after the correction has operated) and over-all regulation are synonymous.

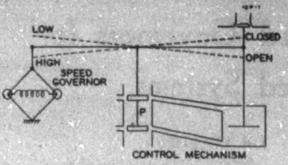

Figure 1. Schematic diagram of speed governing mechanism

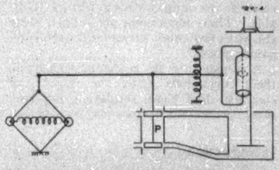

Figure 2. Schematic diagram of speed governing mechanism with compensating dashpot for droop correction, arranged for zero droop

Incremental regulation is the slope of the speed-kilowatt curve passing through 100 per cent speed at the load in question, expressed in per cent of rated speed.

Unfortunately the uniform characteristic shown in figure 4 is not so easy to obtain and requires proper co-ordination in the design of both the speed-position characteristic of the governor and the flow-travel curve of the control mechanism. In the case of a hydro unit, the increase in flow for increased gate openings tends to fall off at the larger gate openings. In this respect most steam turbines have several inlet valves, each having its flow-travel characteristic. A comparison is shown in figure 3 where the dotted curve applies to a hydro unit and the solid curve to a four-valve steam unit.

Mechanisms as in figure 2 have both transient and steady-state incremental regulation. As far as governor influence is concerned, load division between units on a system is determined initially by transient incremental regulation and subsequently by the steady-state incremental regulation. Since most load changes on the larger systems are relatively slow, steady-state incremental regulation is the significant characteristic.

Dead band is the magnitude of the sustained speed change within which change of prime mover input will not be produced. Figure 4 shows two governors with equal dead band, one having broad and the other narrow over-all regulation. It may be seen that the governor having broader regulation will hold its load within a smaller range for a constant frequency and for the same frequency dead band, than the governor with narrow regulation. This dead band is a measure of the sensitivity of the mechanism. A method of simultaneously recording speed on one axis and mechanism movement on the other axis has been developed using apparatus similar to that described in reference 8. When proper interpretation of such records can be made, this method should prove useful in determining the over-all dead band of governing mechanisms while in service.

Supplementary adjustment—Any means employed to adjust externally the prime mover input.

Conclusions

The following conclusions, which apply to the requirements of both steam and hydro units, have been arrived at after having considered operating requirements, nature of load changes on large systems, reliability of operation, simplicity in mechanisms, and ease of maintenance.

1. Dead band should be as small as practicable.
2. Uniform incremental regulation is desirable but not essential.
3. Adjustable regulation is not necessary.
4. Similarity of rates of response is not necessary.
5. Accurate response for supplementary adjustment is desirable.
6. Indications of all adjustments are desirable.

A brief review of the reasons supporting the above conclusions follows:

STABILITY

One of the first and axiomatic requirements is that the mechanism be stable** at all times. A stable governor is one which does not by itself produce or excite an oscillation. A governor with a high degree of, or with good stability, is effective in quickly reducing the magnitude of an oscillation produced by any disturbance. Small dead band, broad incremental regulation, both transient and steady-state, and small time lags all contribute to stability and are largely under the control of the designer. Generally, if the unit is stable for synchronizing, it will be still more stable when connected to a system due to the synchronizing and damping torque action provided by the system. For the same reason a governing mechanism which is poor when operated alone may give no trouble when it becomes part of a system already equipped with good governors.*

---

*Figure 3, reference 7.

**Figures 1–12 inclusive, reference 7.

At the same time a single machine or a number of machines behaving as a group is influenced to a large extent by the damping characteristic of the load, i.e., the change of load per unit of speed change, other conditions being constant.**

Dead Band

Small dead band (small over-all insensitivity) contributes to stability, maintains accurate loads at fixed frequency and gives accurate response to frequency variations. (See figure 4.) Study of this characteristic has convinced us that it is the over-all dead band, rather than dead band of some particular portion of the mechanism, that is the significant factor.†

In a few instances there has been evidence to show that if insensitive governors control the major portion of the system, speed variations may be aggravated by either unnecessary movement of the mechanisms or by insufficient movement caused by the dead band allowing a greater change in frequency before the proper input correction is obtained. These conditions can be overcome by improved design in available mechanisms.

Present evidence indicates that over-all dead band should be made as small as possible just so long as the effort is not carried to the point of requiring undue expense in manufacture, and of requiring undue maintenance in the field to keep that degree of performance. Operating groups can, by tests and analyses, assist the governor designers in establishing the proper economic limit.

Incremental Regulation

The incremental regulation in the normal operating range should be as uniform as is consistent with economical design of the mechanism and efficient turbine operation. By making the incremental regulation as uniform as possible and as large as necessary, stability margin at all valve points is assured and more uniform response to supplementary adjustment is obtained. If the improved uniformity is obtained entirely through mechanism design, more powerful operating cylinders may be necessary or more complicated mechanisms may be required. If the improved uniformity is obtained by increased overlapping in the valve openings, the turbine efficiency is reduced at the valve openings.

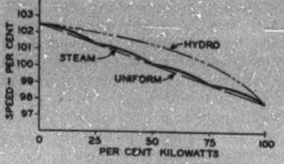

Figure 3. Typical speed-load characteristics for steam and hydro units. Slope of curves at any point is incremental regulation

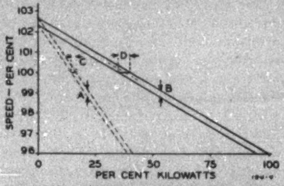

Figure 4. Speed-load curves showing dead band. A and B—Possible speed variation within dead band. C and D—Possible load variation within dead band

Incremental regulation should be as broad as is consistent with reasonable system speed variations. Broad regulation improves stability, contributes to most rapid settling down after a disturbance, and minimizes any tendency for hunting which might be caused by dead band.

Regulation

For steam turbines the maximum over-all regulation which can be tolerated and still meet the present overspeed and emergency trip requirements is about six per cent, and the minimum over-all regulation for stability is in the order of two or three per cent without droop correction. For this reason it is believed that some reasonable over-all regulation in this range can be used for most steam turbine mechanisms, thus avoiding the added complication of adjustable regulation. An advantage in operating on small over-all regulation might be to reduce slightly the duty on the supplementary corrective devices now employed, but it appears as though there is a good chance of creating a wider frequency fringe by attempting to operate the units of an entire system on small over-all regulation, because of the reduced degree of stability obtained.‡

As previously mentioned, hydro governors ordinarily use a large transient regulation in order to obtain stability and droop correction to obtain reasonably small steady-state regulation. Adjustment of this droop is readily obtained. Where adjustable regulation for steam turbines is considered desirable, it may be provided in two ways; first, with a simple mechanism similar to figure 1 where the linkages are adjustable over the two to six per cent range; second, by adding speed droop correction, figure 2, which permits over-all regulations as low as zero, on one machine.

For smaller systems the per cent load changes relative to system capacity are usually larger and maintaining speed is more of a problem. In these cases governing mechanisms which can, if desired, be operated at zero steady-state regulation have a distinct field of usefulness. It is believed, however, that while mechanisms are being built to meet these special conditions on smaller systems, the conditions on the larger systems do not demand such flexibility in speed governing mechanisms.

Rate of Response

The present rates of response of steam and hydro governors are widely different, and this results in a corresponding redistribution of power flow subsequent to load changes. Usually, the sudden load changes on most large systems are relatively small and the major load changes occur at a rate which can be followed by even the slowest mechanisms. In an interconnected system, all active governors respond to all load changes regardless of location in proportion to their ability, and in principle it is the function of supplementary control (manual or automatic, or both) finally to allocate a load change in any area to generation in the same area. Any redistribution of load due to different governor characteristics is so masked by real load changes that it is not considered important to modify designs in order to match characteristics.

Matching characteristics of steam and hydro units would mean slowing down steam turbine governor response to approach that dictated by hydraulic limitations on hydro units, whereas actually in the interest of limiting overspeeds and improving stability it appears desirable to make steam governor response as rapid as is possible without complicating the mechanism. However, in this regard there is no necessity of attempting to make governors which are responsive to rate of change of speed, e.g., inertia governors, since overspeed and stability requirements can both be adequately met with a pure speed responsive mechanism.

---

*Figure 11, reference 7.

**Figures 3 and 4, reference 7.

†Table 1, reference 7.

‡Figures 3 and 14, reference 7.

Terminal frequency has been suggested to provide speed indication for the governor. This method has no advantages so far as performance is concerned over using shaft speed, but it does have at least two distinct disadvantages, both based on the probability that during out-of-step conditions, it may not indicate the actual speed of the unit. As a result, first, in the case of a turbine generator, a separate pre-emergency device to prevent tripping the emergency on overspeed would be required; second, the unit is not intelligently helped to pull back into step. The use of terminal drive has been generally limited to small hydro machines in locations where these disadvantages are not important.

System Short Circuits

In transient stability calculations of systems (studies of the ability of generators to remain in synchronism after a disturbance), governor performance is usually neglected and this assumption gives only slightly pessimistic results for the amount of power which can be transmitted through a short-circuit disturbance.

Fast switching is being commonly used and with breaker speeds now commercially available, stability during short circuits at practical loadings for transmission lines is possible, so that very little gain can be expected through improved governor performance during this short interval. The governing mechanism will do its share if it assists in damping out the subsequent synchronous oscillation.

Out-of-Step Conditions

Out-of-step operation has occurred usually as a result of too slow clearing of a severe fault. When the fault is finally cleared, the generator or station is running faster than the rest of the system. If hydro units are involved, large overspeeds may occur, and system relays will probably trip on overcurrents before the units will resynchronize themselves, even if supplementary means are employed.

Steam units, on the other hand, have faster governing mechanisms, much better induction torque characteristics due to the solid rotor generator construction and a stronger electrical tie to the system and load. Therefore, the units settle down soon at a low overspeed. This situation alone gives a good opportunity for self-resynchronizing. As a supplementary measure, increasing the field strength is probably one of the easiest and best assurances of resynchronizing, although some have advocated reducing the input torque.[18]

Tie-Line Load Swings

The normal tie-line power fluctuations due to sudden load changes cannot be appreciably reduced by governor operation, regardless of rate of response, since the initial power flow is largely determined by the system and tie-line impedances, later modified by inertias and finally determined by governor action. Gradual load changes will be divided according to composite governor characteristics of various portions of the system and later modified by supplementary control.

In the steady-state condition most tie lines have a sustained power oscillation at the natural frequency of the interconnected groups. These power oscillations are usually a small percentage of the tie-line capacities and alone represent no problem. With these power oscillations there is associated a speed oscillation of small magnitude. Experience and our studies[7] indicate that the characteristic of these swings may be influenced by governor action, but usually should be within reasonably satisfactory limits with ordinary governor performance. In those cases where the governors tend to excite unnecessary power oscillations, proper adjustment of the governor characteristics, for example, broadening the regulation, should eliminate the tendency.

Adjustment and Indications

Supplementary adjustment is provided on all speed governors and may be used for either manual or automatic correction. This adjustment should be arranged so that reasonably uniform response is assured throughout the operating range.

Gate position indication has been available on hydro units for some time and indication of operating piston position on steam units, with valve opening points marked, has been suggested. Gate indication on a hydro unit is often more useful than a wattmeter, particularly on a variable head installation and on a steam unit it is desirable to avoid operation at partial valve openings. With the more recent turbines a recorder is being provided which records speed of the unit prior to synchronizing and which records cam shaft position after synchronizing. This arrangement gives a complete record of the manner in which the machine has been brought up to speed and loaded.

Load-limiting features are furnished on most turbines and are still being used to some extent. This feature is particularly useful in maintaining a fixed load on a machine connected to a system where the frequency is allowed to vary through wide limits. On most large systems, today, frequency is normally held within a 0.1-cycle band by means of supplementary control. Any machine equipped with a five per cent speed governor will change load by only three per cent in response to such a frequency change and most steam operators agree that this is essentially fixed load, for machines carrying a reasonable load. In general, the frequency fringe on a system is reduced by increasing the percentage of machines on governor control, and to this end load limit as such may be advantageously discarded except as a back-up measure to prevent severe overloads on boilers and associated equipment during system emergencies.

Summary

The conclusions which have already been enumerated and discussed apply to governing mechanisms of prime movers on the larger systems. For smaller systems governing mechanisms which can, if desired, be operated at zero steady-state regulation, have a distinct field of usefulness. For governing mechanisms on the large systems, emphasis should be placed on obtaining uniform incremental regulation, accurate response for supplementary control, and small dead band. The experience and judgment of the operating groups will be of assistance in determining the economic limit, beyond which the design cannot be justifiably carried.

Analysis of Short-Circuit Oscillograms

W. W. KUYPER
ASSOCIATE AIEE

Summary

METHODS of analyzing the oscillograms of short circuit currents of synchronous machines, in accordance with the two reaction theory, are presented in this paper. Differences between the results found here and the more generally accepted equations, based on symmetrical components, are pointed out.

Introduction

The analysis of short circuit oscillograms to obtain synchronous machine reactances is usually made by means of the equations developed from symmetrical component theories. These equations have been employed by previous writers on the subject and have been incorporated in published standards. Because symmetrical component methods usually start from the assumption of sinusoidal currents of single frequency in the armature, and because it is known that short circuit currents depart appreciably from the simple sinusoidal form, it is desirable to know the effect of removing the assumption of sinusoidal currents on the equations used in the analysis of short circuit oscillograms.

The two reaction theory of synchronous machines, as developed by Doherty and Nickle[1,2], permits a calculation of the harmonics of armature current. The method has been widely used to determine operating characteristics of machines; but the application to the calculation of machine quantities from oscillograms of short circuit currents is not well known. It is the purpose of this paper to show how the two reaction theory applies in such a determination of reactances.

The equations of armature current as previously published are restated here. From these equations, expressions for the envelopes of the currents are written. These envelopes have certain slight limitations which will be mentioned later, but, except in rare cases, they may be drawn readily on the oscillogram. The equations of the envelopes permit a simple statement of the relations between the voltages, currents and reactances.

The two reaction theory has been checked by test within the limits of the assumptions under which it was derived. The results herein described have about the same limitations and the same degree of applicability. While it is true that the presence of saturation, resistance and nonsinusoidal windings cause appreciable departures from the case of the ideal machine here treated, knowledge of the characteristics of the ideal machine is basal to an understanding of the effects of these complicating factors.

Three-Phase Short Circuit

Doherty and Nickle[2] give the equation of the armature current after a sudden three phase short circuit at the terminals of the machine. It may be shown that the current in one phase, when the effect of an amortisseur is included, is defined by the following equation.

$$i=\frac{e_0F_3}{x_d''}\cos(t-\alpha)-\frac{e_0(x_d''+x_q'')}{2x_d''x_q''}A_3\cos\alpha+\frac{e_0(x_d''-x_q'')}{2x_d''x_q''}A_3\cos(2t-\alpha)\text{ times normal peak current}\quad(1)$$

where

i = per unit current at any time t.

e_0 = per unit voltage before fault (peak value).

t = per unit time, $t=0$ at time of fault. One per unit time is required for the machine to progress through one electrical radian.

α = electrical angle between centerline of armature and centerline of field at the time of the fault.

x_d = per unit direct axis synchronous reactance.

x_d' = per unit direct axis transient reactance.

x_d'' = per unit direct axis subtransient reactance.

x_q'' = per unit quadrature axis subtransient reactance.

σ_a = decrement factor of the armature.

σ_f' = decrement factor of the field, transient.

σ_f'' = decrement factor of the field, subtransient.

$A_3=\epsilon^{-\sigma_a t}$

$$F_3=x_d''\left[\frac{1}{x_d}+\left(\frac{1}{x_d'}-\frac{1}{x_d}\right)\epsilon^{-\sigma_f't}+\left(\frac{1}{x_d''}-\frac{1}{x_d'}\right)\epsilon^{-\sigma_f''t}\right]$$

Consider the case, $\alpha=0$, which gives a fully offset wave.

Subject to conditions stated later, two equations representing the envelope may be written as follows:

$$\text{Envelope line number 1}=\frac{-F_3-A_3}{x_d''}e_0\quad(2)$$

$$\text{Envelope line number 2}=\frac{F_3-A_3}{x_d''}e_0\quad(3)$$

It may readily be verified that the slopes and values of equation 2 at $t=\pi+2n\pi$ are identical with the slopes and values of equation 1 at $t=\pi+2n\pi$. Similarly, the slopes and values of equations 3 and 1 are equal at $t=0+2n\pi$. Therefore, unless there is more than one maximum per half cycle, they are the envelopes as usually defined. (This latter condition will be discussed later.)

The difference obtained by subtracting equation 2 from equation 3 gives the width of the envelope,

$$\text{width of envelope}=\frac{2F_3e_0}{x_d''}\text{ (in terms of normal peak current)}\quad(4)$$

The d-c component of the current is given by the second term of equation 1. For a fully offset wave,

$$\text{d-c component}=\frac{A_3e_0(x_d''+x_q'')}{2x_d''x_q''}\quad(5)$$

Paper 41-2, recommended by the AIEE committee on electrical machinery and presented at the AIEE winter convention, Philadelphia, Pa., January 27–31, 1941. Manuscript submitted May 23, 1938; made available for preprinting October 23, 1940.

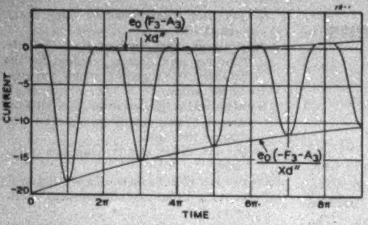

Figure 1. Three-phase fault current and envelope, equations 1, 2, 3

$\alpha=0$
$x_d''=0.10$ per unit
$x_q''/x_d''=3.0$
$x_d'=0.15$ per unit
$x_d=1.00$ per unit
$e_0=1.0$ per unit
$\sigma_a=0.0265$ per unit
$\sigma_f''=0.106$ per unit
$\sigma_f'=0.0076$ per unit

This component is often considered to be traced by the midpoint of the envelope lines. That this is not the case is evidenced by averaging equations 2 and 3, which determines the midpoint:

$$\text{Median line between envelope lines} = \frac{A_3 e_0}{x_d''} \tag{6}$$

A study of equation 4, together with the expression given for F directly after equation 1, shows that the envelope width at $t=0$, when extrapolated from the subtransient region, is $2e_0/x_d''$; when extrapolated from the transient region it is $2e_0/x_d'$. These relations have been shown only for the case of $\alpha=0$, giving a fully displaced wave. They also hold at $\alpha=180$, but not for a fault at any other point in the cycle, unless $x_d''=x_q''$.

If the rates of change of the decrement factors, A_3 and F_3, in equation 1 (for $\alpha=0$) are assumed to be zero (in commercial machines they are small compared to the rates of change of the sinusoidal terms) the conditions for maxima and minima of current are:

$$\sin t=0 \tag{7}$$

$$\cos t=\frac{x_q''}{x_q''-x_d''}\,\frac{F_3}{2A_3} \tag{8}$$

The roots of equation 7, substituted into equation 1, with $\alpha=0$, yield the envelope lines, equations 2 and 3. Equation 2 is derived by setting $t=\pi, 3\pi, 5\pi$, etc.; equation 3, by setting $t=0, 2\pi, 4\pi$, etc. These envelopes have previously been shown to pass through the maximum and minimum points (at 0, 180, 360 deg., etc.) of the current wave, and to have the same rates of change as the current at these points.

Roots of equation 8 exist only when

$$|2A_3(x_q''-x_d'')|>|F_3 x_q''| \tag{9}$$

It is apparent that when $x_q''-x_d''$ is small, only one maximum exists per half cycle. Under such conditions the envelope may be drawn on the oscillogram in the usual way and equations 2 and 3 will represent the envelope.

When the inequality (9) is satisfied, equation 8 can be solved and additional maxima are introduced. However, the envelope represented by equations 2 and 3 can still be drawn, and the relations derived from these equations still hold. The manner of constructing the envelope for such conditions is indicated in figure 1.

Calculation of peak currents may be made from the above equations. Consider the first negative peak of figure 1. It is apparent that the maximum current occurs just previous to the point of tangency with the envelope (the 180° point) and that for most purposes this peak value may be approximated by the value at 180°. From equation 1 or 2, this value is

$$\text{peak current}=e_0\,\frac{A_3+F_3}{x_d''}\ \text{times normal peak current} \tag{10}$$

Disregarding the small increase in this value mentioned above, the value of peak current given in equation 10 can be exceeded only if x_d'' is appreciably greater than x_q''. Under this condition the sign of the second harmonic is reversed and the double maximum which is shown in figure 1, near the 360° point, occurs near the 180° point. An examination of figures 1, 2, and 3 shows how the change of sign on the second harmonic component (see equation 1) changes the position of the double maximum. The condition, $x_d''>x_q''$, is uncommon in commercial machines and need not be considered further.

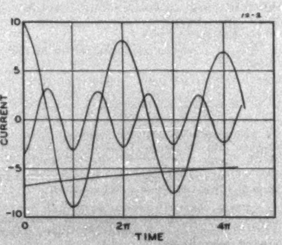

Figure 2. Components of figure 1

The above discussion and equations are valid only for the case $\alpha=0$ (or 180°), which results in a fully offset wave. For a fault at any other point in the cycle, no similar simple relations have been written. However, the extent to which the wave shape changes with change of α is indicated in figure 4. The envelope lines for the case, $x_q''=x_d''$, (where envelope width is $2F_3/x_d''$) are shown to indicate the amount of variation from the simple case which may be expected.

Single-Phase Case

Nickle, Pierce and Henderson[3] give the equation of armature current for single phase short circuit at the machine terminals:

$$i=\frac{3e_0}{k}\,\frac{F_1\cos(t+\alpha)-A_1}{H} \tag{11}$$

or,

$$i=\frac{3e_0}{2k}\,\frac{2F_1O}{x_d''+x_2}-\frac{A_1}{x_2}E \tag{12}$$

where

$k=1$ for L-N, 3 for L-L fault

$H=(x_d''+x_q'')+(x_d''-x_q'')\cos 2(t+\alpha)$

$A_1=\epsilon^{-at}\cos\alpha$

$$F_1=\frac{x_d''+x_2}{x_d+x_2}+\frac{(x_d''+x_2)(x_d-x_d')}{(x_d+x_2)(x_d'+x_2)}\epsilon^{-\sigma_f't}+\frac{x_d'-x_d''}{x_d'+x_2}\epsilon^{-\sigma_f''t}$$

$O=\cos(t+\alpha)+b\cos 3(t+\alpha)+b^2\times\cos 5(t+\alpha)+\ldots$

$E=1+2b\cos 2(t+\alpha)+2b^2\cos 4(t+\alpha)+\ldots$

$$b=\frac{x_2-x_d''}{x_2+x_d''}=\frac{\sqrt{x_q''}-\sqrt{x_d''}}{\sqrt{x_q''}+\sqrt{x_d''}}$$

$x_2=\sqrt{x_d''x_q''}$

For a line-to-neutral fault use $x_d''+\frac{x_0}{2}$ for x_d'' etc.

Similar to the three phase case, the equation of the envelope of the single phase fault current is

$$\text{Envelope line number 1}=\frac{3e_0}{k}\left[\frac{-F_1-A_1}{2x_d''}\right] \tag{13}$$

$$\text{Envelope line number 2}=\left[\frac{3e_0}{k}\,\frac{F_1-A_1}{2x_d''}\right] \tag{14}$$

$$\text{The width of the envelope is }\frac{3e_0}{k}\,\frac{F_1}{x_d''} \tag{15}$$

The extrapolation of the subtransient part of the envelope to $t=0$ yields $\frac{3e_0}{kx_d''}$ times normal peak current. The extrapolation of the transient part of the envelope to $t=0$ yields $\frac{3e_0}{kx_d''}\cdot\frac{(x_d''+x_2)}{(x_d'+x_2)}$.

Similar to the three phase case, unless

$$-1 \leq \left[\frac{A}{F}+\sqrt{\frac{A^2}{F^2}+\frac{x_q''}{x_d''-x_q''}}\right] \leq 1 \text{ and is real} \tag{16}$$

the envelope of equations 13 and 14 is drawn in the usual way. If these conditions do exist, there will be more than one maximum per half cycle, but the envelope lines may still be drawn tangent at the 0° and 180° points, similar to figure 1, which treats the three phase case.

The peak value of the single phase fault current may be written from equation 13. The absolute peak value occurs when the wave is fully offset

$$\text{peak value of current} = \frac{3e_0}{k}\,\frac{F_1+A_1}{2x_d''} \text{ times normal peak value} \tag{17}$$

Certain limitations must be applied to equation 17 similar to those applied to equation 10 which governs the three phase case. Equation 17 can be used with confidence where $x_d''<x_q''$; however, where x_d'' is appreciably greater than x_q'', the absolute peak value of current will occur before the 180° point (assuming a totally offset wave) and may be appreciably greater than the value given by equation 17. This possibility is pointed out but not investigated further because of the improbable nature of the condition.

Conclusions

1. In a single phase line-to-line short circuit the width of the envelope (in terms of normal peak value of current) extrapolated to the time of the fault is $\frac{\sqrt{3}e_0}{x_d''}$. The reactance, x_2, does not appear as it does in the symmetrical component method of analysis, $(2\sqrt{3}e_0)/(x_d''+x_2)$. In a single phase line-to-neutral short circuit the extrapolated value of the envelope width is $3e_0/(x_d''+x_0/2)$.

2. An extrapolation to the time of the fault of the transient part of the envelope of a line-to-line fault shows the width of the envelope to be

$$\frac{\sqrt{3}e_0}{x_d''}\,\frac{x_d''+x_2}{x_d'+x_2}$$

The above relations developed from the two reaction theory indicate that it is not possible to determine x_2 from the subtransient part of the envelope of the current of a line-to-line fault. Any attempt to use the transient part of the envelope to find x_2 is very liable to errors arising from errors in the determination of x_d'' and x_d'.

Similarly, unless x_0 is very large, its accurate determination from the envelope of current of a line-to-neutral fault is not practicable.

3. The peak current on a line-to-line fault is $\sqrt{3}e_0\frac{F_1+A_1}{2x_d''}$ times normal peak current, where A_1 and F_1 are decrement factors, equal to unity at the time of the fault.

The peak current of a line-to-neutral fault is $3e_0\frac{F_1+A_1}{2x_d''+x_0}$.

It is of interest to note that x_2 does not enter in the above expressions as it does in the equations resulting from the use of symmetrical component methods. In every case where $x_2>x_d''$ the symmetrical component equations apparently calculate too low a value of peak current.

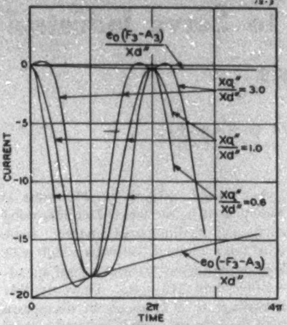

Figure 3. Change of wave shape with change of x_q''/x_d''

Other constants same as in figure 1

4. In an ideal machine, when the armature current in a three phase short circuit is fully offset, the envelope width at the time of the fault is $\frac{2e_0}{x_d''}$ times normal peak current when extrapolated from the subtransient region and $\frac{2e_0}{x_d'}$ when extrapolated from the transient region. In general, this is not true when the fault is made at any position of the rotor other than that which gives a fully offset wave.

In most commercial machines the ratios of machine constants are such that the degree of offset is of little practical importance in the determination of reactance from oscillograms of three phase short circuits. However, in view of the fact that several published statements prefer a symmetrical current wave, the above conclusions preferring a fully offset wave are of interest.

The conclusions given here are dependent on a prescribed method of drawing the envelope, which is explained in the body of the paper. In the majority of commercial machines this fact presents no great limitations.

The equations presented above are dependent on the assumption of an ideal machine: negligible resistance; negligible saturation; sinusoidal windings; and a sinusoidal variation of armature subtransient reactance with rotor position. The presence of resistance alters the phase relationship between the current harmonics, although it does not usually cause impedances to be appreciably greater than the associated reactances in short circuits at the machine terminals. Saturation may be partially treated by employing saturated values of the reactances; but the wave form distortion due to the changing values of reactance during the fault and the nonsinusoidal distribution of windings may cause appreciable departures from the calculated wave shape, and thereby vitiate in part the conclusions of this paper. However that may be, a more thorough understanding of the ideal machine relationships should be an aid to more accurate determination of synchronous machine constants from test.

Secondary Networks to Serve Industrial Plants

C. A. POWEL
MEMBER AIEE

H. G. BARNETT
ASSOCIATE AIEE

THE design of distribution systems for industrial plants will always constitute individualized problems. There is little hope that any particular form of distribution will be applicable to all industrial plants because the processes of manufacture and the arrangement of buildings differ widely depending on circumstances. There are, however, certain fundamental advantages to the network system of distribution which justify a much wider use than it has found to date. By far the greater part of factory distribution is still of the radial type and the network system must compete with the radial system in economy, reliability, and flexibility. The purpose of this paper is to show that it can do so successfully.

Assuming that the product of the factory is such that a relatively large number of small and medium-sized motors are required rather than a few large ones, it will be found that the physical location in the factory of the various machines is not of such importance in the layout of the distribution scheme as the total connected load, the diversity factor and the over-all power factor, and it is on its ability to take advantage of diversity that some of the economy of the network system rests.

The information available on the load density of factories is quite fragmentary. For the more common products of manufacture it varies from 5 to 30 kw per 1,000 square feet, 10 to 20 being the value mostly encountered, although in exceptional cases it may go as high as 100 kw. Load density should not be confused with the rating of the installed motors and utilization devices. The diversity between the various loads will considerably reduce this figure, and the "demand-factor," that is, the ratio of the maximum demand over a period of time to the sum of the utilization device ratings, which is of significance in determining the transformer capacity to be installed, may be 50 per cent or less.

A nominal voltage of 440 volts is widely used in the larger factories using small and medium-sized motors. Some mills have adopted 550 volts which with long radial feeds naturally has an advantage over 440 volts. However, this advantage to a large extent disappears with the network system and 440 volts is preferable. Experience with 208-volt metropolitan networks indicates that motors of 750 horsepower and even larger can readily be started up on a 440-volt network without disturbance.

It is desirable that the 440 volts be maintained at the motor locations without much deviation either up or down, and since the regulation in the network is better than in most existing radial distribution systems, the voltage at the supply source should not be much higher than 440 volts.

In the conventional 208-volt city network, the lighting is carried out at 120 volts with the units connected between the outside conductors and neutral. With 440 volts maintained on the suggested factory network the same possibility exists if 250-volt lighting can be used with safety. The type of lighting that might be operated successfully on 250 volts would include primarily the high-intensity mercury lamps of 250- and 400-watt sizes in high-bay reflectors (figure 1), and for intermediate mounting heights the larger fluorescent lamps.

It is generally found necessary in modern manufacturing methods to change tool machinery and processes around in the factory from time to time to meet market conditions, but it is also true that such changes cannot be of a radical nature as the manufacturing possibilities are limited by the type and size of the building. It is, therefore, advisable in designing the distribution system to make the power available at a number of points conveniently spaced throughout the factory building without too much regard to the detailed location of the individual tools.

The network is well adapted to supplying power to such points, and where the total load is 500 kva or more a network, either a distributed or spot network, will frequently be justified. As the total load increases the network becomes more decisively economical.

It is convenient to divide networks into spot networks and distributed networks. A spot network consists of a bus supplied through two or more network transformers and protectors over two or more primary feeders as shown in figure 2. It may be used in the smaller plants or large commercial buildings where the demand is relatively light and distances short. The distributed network on the other hand comprises a secondary grid, the junction points of which are supplied through network transformers and protectors from two or more primary feeders, as shown in figure 3. There is practically no limit to the load that can be carried on such a grid, and spot networks grow into conventional networks as the load increases.

It is not possible to lay down any definite rules regarding the number of supply points and secondary ties that should be included in factory networks, nor the best

Figure 1. General lighting at an average intensity of 25 foot-candles supplied by three 40-watt daylight fluorescent lamps in each luminaire

---

Paper 41-48, recommended by the AIEE committee on industrial power applications, and presented at the AIEE winter convention, Philadelphia, Pa., January 27-31, 1941. Manuscript submitted November 15, 1940; made available for preprinting December 11, 1940.

C. A. Powel and H. G. Barnett are both in the industry engineering department of the Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.

size of copper to use. This will depend on the load density and arrangement of the manufacturing aisles in the factory buildings. It can be said, however, that when high current-carrying capacity is required in the secondary mains it is preferable to limit the size of conductor and use two or more smaller conductors in parallel instead of a single large conductor. For example, two 4/0 conductors in parallel provide more carrying capacity than a 500,000-circular-mil conductor and also provide better voltage regulation for a given current at the power factors usually prevailing in distribution systems. Furthermore, in case of a fault in one of these parallel cables, the limiters will isolate it without breaking the network.

The ease with which increasing loads or rearrangement of existing loads in the plant can be taken care of is one of the outstanding advantages of the network system. The addition of a transformer at a junction point of the grid can be made at any time without interruption of service, the relatively small self-contained transformer units with the network protector mounted on it requiring very little space.

Further advantages of the system are reliability, good regulation, and high economy. Reliability is improved by virtue of the fact that the grid is supplied from all the feeders supplying the factory and through all the transformers. The loss of a feeder or transformer would, therefore, pass unnoticed as far as the factory operations are concerned. The regulation is better and the disturbances due to starting up motors are less because of the multiplicity of paths over which the current flows.

In most factories supplied through radial systems of distribution it is usual to put in a substation at some convenient location with one or more transformer banks stepping down the voltage from the power company's primary distribution voltage. A full capacity primary circuit breaker and a 440-volt distribution bus are provided in the substation from which a number of radial feeders are run to the distribution centers in the factory through suitable circuit breakers. The disadvantages of this scheme are obvious.

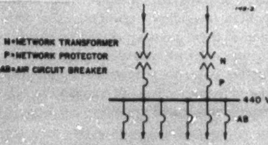

Figure 2. **Spot network**

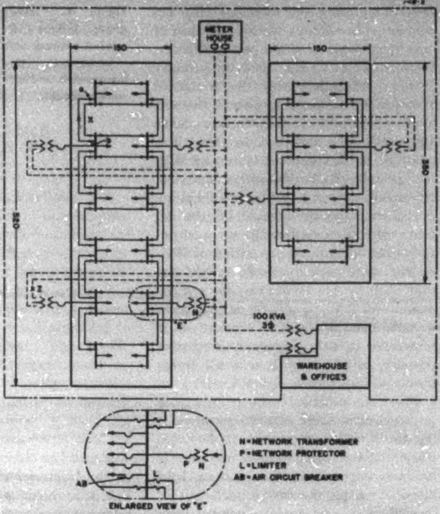
Figure 3. **Distributed network for factory buildings**



All the breakers must have high rupturing capacity, the low-voltage, that is, the heavy-copper, feeders are of considerable length before reaching the utilization points and maximum economy is obtained only if it is known beforehand exactly what the power requirements are likely to be. Experience has shown that this assumption cannot be made and consequently the transformer capacity installed is usually very much greater than necessary.

A network for a typical factory consisting of two manufacturing and assembly buildings and a five-story office and warehouse building is shown in figure 3. The supply from the utility is over two cables at 13,200 volts, 60 cycles. The maximum demand is 2,500 kva. For taking care of the shop load six transformers of 450 kva, 13,200/440 volts, equipped with primary change-over switches and secondary protectors are provided, and for the warehouse load two 100-kva, 13,200/208-volt, network transformers.

The transformers may be standard oil-filled transformers with network protectors mounted on them, similar to those used in metropolitan distribution systems. In this case they will be placed outside of the factory buildings, either in the open or in vaults. In many cases a more economical installation can be made with air-cooled transformers placed inside the factory buildings, the transformers having mounted at one end an open-type network protector and on the other end a primary switch, the entire unit being enclosed in a single-ventilated housing as shown in figure 4. The network protector of each transformer would be connected to a short bus from which the utilization devices would be supplied through air circuit breakers. These busses would be interconnected among themselves throughout the factory by means of twin cables so as to form the network as indicated in figure 3.

The cardinal principle of the 120/208-volt network system is that secondary faults are burnt clear by the fault current. Experience has shown that while this is entirely desirable and feasible with the low voltages and heavy amperages used in metropolitan distribution, it must be modified for application to factory distribution. At 440 volts secondary faults are not self clearing and it becomes necessary to use protective fuses or limiters at each end of each secondary conductor to definitely clear faults and limit the damage to that section of cable.

With the arrangement proposed it will be seen that an electrical fault anywhere in the plant will leave the major operations undisturbed. The failure of a consuming device will be cleared by its own breaker. A fault on one of the cables forming the network, for instance at *X*, will cause the limiters or fuses *a* and *b* to blow to isolate the fault. These are the only two limiters to carry the full-fault current and they will, therefore, clear before any other limiter opens. A failure of the transformer or of the primary feeder, for instance at Z, will cause the primary breaker associated with the feeder or transformer to open and also all the network protectors on that feeder. Since the network is designed so that there must be no interruption of service with one primary feeder out of commission, this means that with two feeders the spare transformer capacity would be 100 per cent; with three feeders the spare capacity would be 50 per cent; with four feeders the spare capacity would be 33.3 per cent, and so on. With two feeders the amount of spare capacity is so great as to become uneconomical. Therefore, it is preferable to use a manual throw-over primary switch on each network transformer as indicated in figure 3.

There is a practical limit to the saving in transformer spare capacity by increasing the number of primary feeders, because with increasing number of feeders it becomes impossible to get uniform load division among the transformers left in service when one feeder is out. Also, when more than six feeders are used it is frequently necessary to consider that two feeders may be out of service at once; consequently, seven or eight feeders may require more transformer capacity than four or five feeders. For very large plants this is a very practical consideration and it may dictate the use of two networks in preference to a single network.

The quality of service, that is, reliability and voltage regulation, rendered by the secondary network is better than that provided by any other a-c distribution system. Whether the network is economical in a particular case depends on the degree of reliability required, the amount of flexibility required to meet load growth or change, and the load density and total load to be served.

Whenever it is necessary to provide greater reliability than can be obtained from a simple radial system the network will always be economical, particularly for relatively large loads. To get improved reliability in a radial distribution system it is necessary to use duplicate feeders, manual or automatic throw-over switches or breaker, load-transfer switches, sectionalizing switches or fuses, or other schemes for reducing the duration of outages. For faults on a primary feeder or in a transformer even these special radial schemes do no more than reduce the duration of the outage to a momentary interruption of service, which in many factories may not be permissible. Faults in main secondary circuits will interrupt service to all the load on that circuit until the fault can be repaired. The secondary network eliminates outages due to primary faults and most secondary faults will not interrupt service to any load. The switching equipment required in either manual or automatic radial schemes to provide duplicate power supply is expensive.

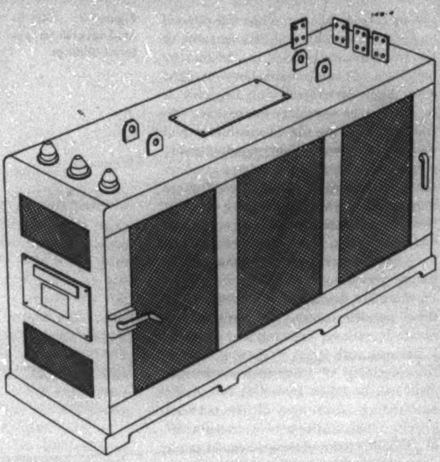


Figure 4. Three-phase indoor air-cooled network unit—transformer, primary switch, and network protector

The flexibility of the secondary network is an economic advantage. Changes to provide for load growth or changes of load concentration from one part of a plant to another usually can be made by simply installing or moving transformers to meet new load conditions. In the radial scheme any changes in load may necessitate not only changing the transformer capacity but also changing a considerable amount of secondary circuits. Since changes in processes and machines frequently are made in industrial plants, this characteristic of the network system will represent a large saving in many cases.

A comparison of the initial cost of a radial system and of a network system was made for the factory shown in figure 3. In the case of the radial system of distribution a small substation was provided at the upper end of the property comprising a transformer bank of four single-phase units of 833 kva each and primary switchgear consisting of two 500,000-kva, 15-kv oil-circuit breakers with necessary control panels. On the secondary side of the transformer bank a breaker was installed in the leads between the transformer and the 440-volt secondary bus. Five 440-volt radial feeders supply distributing points suitably located in the factory buildings.

In the case of the network system of distribution the primary 13,200-volt cables are brought to the six 440-volt network transformers of 450-kva each. Normally three transformers are connected to one cable and three to the other. In case of a fault on one primary cable the three transformers on the sound cable will be overloaded for the short period of time necessary to operate the primary switches to remove the three transformers from the fault cable and put them onto the sound cable.

With this layout it was found that the network system of distribution showed a saving of approximately 20 per cent over the radial system. It should be noted that in both systems primary circuit breakers were included at the point where the primary cables enter the property. With the network system where a group of primary feeders supply one or more industrial plant networks, it is questionable if these primary breakers are necessary in view of experience with power supply to large commercial buildings from metropolitan secondary networks. The omission of these primary circuit breakers on factory network systems would materially further lower the investment required for the network system as compared to the comparable radial system.

An Electron Microscope for Practical Laboratory Service

DIRECT observation of extremely minute objects is of great value to both science and industry. Consequently a great deal of time and effort has been spent developing and perfecting optical instruments for making such observations. The modern light microscope is capable of rendering visible detail which is as fine as 0.00002 centimeter. Since the limit of resolving power of the normal eye is between 0.01 and 0.02 centimeter, the maximum useful magnification with these instruments is 1,000 to 2,000 diameters. Where ultraviolet light is used, the useful magnification can be increased to about 3,000 diameters.

The limits discussed above are not due to imperfections in the optical systems or lenses, but are fundamental in nature. It has been shown quite generally that diffraction effects at the object determine the least separation between points or lines on the object which can be resolved. On the basis of this limitation, the resolving power (for lines) at the object is given by

$$d = \frac{0.5\,\lambda}{\mu \sin \alpha}$$

where λ is the wave length of the radiation illuminating the object; μ the index of refraction of the medium in which the object is imbedded, and α the half angle of the cone of light entering the optical system. For visible light the smallest wave length is about 4,000 angstrom units, and the maximum index for the fluid immersing the object is 1.7; therefore, since $\sin \alpha$ cannot be greater than unity, the minimum distinguishable distance is seen to be about 1,200 angstrom units.

From the foregoing it is evident that to extend the range of observation, it is necessary either to find an immersion substance which has a very much greater index of refraction, or to illuminate the object with rays having a much shorter wave length. No known optical medium has an index of refraction greater than two or three, and no liquid suitable for use with an immersion objective has an index greater than the figure used above, namely, 1.7. Therefore, there is little hope of achieving high resolution in this direction. Electromagnetic radiation in the form of X rays and gamma rays has a wave length much shorter than that of visible and ultraviolet light used at present in microscopy. However, due to the fact that lenses or reflectors cannot be made for this portion of the spectrum, advances in this direction are also barred.

For many years the problem of observing appreciably finer detail appeared to be incapable of solution. The search, however, had been restricted almost entirely to the realm of optics, whereas actually the solution lay in an entirely different field—electronics. A little less than 15 years ago it was found that the path of electrons in electric and magnetic fields could be described in terms which are analytically equivalent to those of optics. By means of this electron optical equivalence, it was shown that axially symmetric electric or magnetic fields had the properties of optical lenses, and, consequently, that it is possible to form electron images in the same way that light images can be formed.

At about the same time, the discovery was made that any material particle in motion had associated with it a characteristic wave length. For electrons this wave length, in terms of their velocity expressed in electron volts, is given by the following relation:

$$\lambda = \sqrt{\frac{150}{V}} \text{ angstrom units}$$

On the basis of this equation, electrons moving with a velocity corresponding to 60 kv have an effective wave length of 0.05 angstrom unit, or only about 1/100,000 that of light. In other words, suitably designed electronic systems employing these high-speed electrons should be capable of extremely high resolving power.

These two concepts led directly and logically to the idea of an electron microscope based on the same principles used in an optical microscope. Such an instrument employs condenser, objective, and projection lenses, performing the same functions as the corresponding elements in the light microscope, but the lenses, instead of being made of glass, are formed by axially symmetric electric or magnetic fields. During the past 10 years, instruments of this type have been investigated in detail in various parts of the world. As a result, the electron microscope has been developed to a point where it is capable of a useful magnification nearly two orders of magnitude greater than the ordinary light microscope. Until recently, the development has been in the hands of physicists, and the instruments built were designed almost entirely for the purpose of studying the microscope itself. However, the microscope has now progressed beyond this stage, and has become a research tool of great potential value.

The problem of realizing this potential value is one for engineers, and as such, its solution was undertaken in the RCA Research Laboratories at Camden, New Jersey. Starting from the basic physical principles, it was necessary to work out the design of an instrument which would be sufficiently simple in operation and rugged in construction to be operated by the average worker in any scientific or industrial research laboratory, and would not require the supervision of a trained physicist. An RCA microscope, developed by L. Marton,[1] which fulfills in part the requirements of a generally practical microscope, was described in an earlier number of ELECTRICAL ENGINEERING.[2] This microscope, although very satisfactory from the standpoint of resolving power, proved to be somewhat difficult to operate and very critical in adjustment and alignment. Furthermore, the instrument and associated equipment occupied a large amount of space.

Work on the electron microscope was continued in order to overcome the objectionable features mentioned above. As a result, an instrument has now been developed by J. Hillier which is completely self-contained, occupies only a small amount of space, and is so simple to adjust and operate that it can be readily handled by any capable laboratory technician.[3] In addition, the microscope incorporates an improved type of magnetic objective lens which increases its resolving power for specimens supported in the manner described below.

Figure 1 is a photograph of the complete microscope. The unit includes not only the microscope itself, but also the regulated power supplies providing the 60-kv over-all voltage and the current for

Figure 1. RCA electron microscope

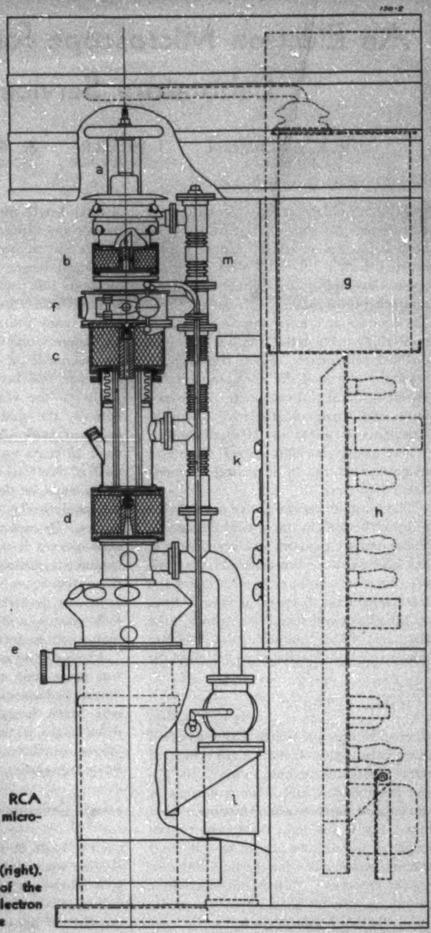

Figure 2 (right). Diagram of the RCA electron microscope

the three magnetic lens coils. The oil diffusion pump for maintaining the required vacuum within the instrument is also contained in the unit.

A simplified drawing is given in figure 2, which shows the construction of the microscope. The electrons used in the imaging process are supplied from the electron gun (*a*), containing a thermionic cathode which is maintained at 60-kv negative with respect to ground, and a final anode at ground potential. Between the two are disposed the electrodes required for governing the electron paths. The electrons leaving the gun have their full velocity, corresponding to 60 kv.

The condenser lens (*b*), which consists of an iron-clad coil with pole pieces shaped to give the required magnetic field, causes the electrons to converge upon the specimen held a few centimeters below it. The condenser, like the condenser lens of a light microscope, can be used to control the angular aperture of the illumination at the specimen.

After passing through the specimen, the electrons enter the objective lens (*c*). This lens deflects the electrons leaving the specimen in such a way as to focus them into a magnified intermediate image of the specimen. This image is formed directly above the projection lens (*d*). The objective, like the condenser, is an armored coil, but the pole pieces are, of course, different in design to meet the requirements of this element. The design of the object lens is very important, and the success or failure of an electron microscope depends to a large extent upon the skill and accuracy with which it is designed and constructed.

The final image is formed from the por-

Figure 3. Air lock and object chamber

tion of the intermediate image which passes through the projection lens (*d*) and is reimaged in the plane of the observing screen or photographic plate at (*e*). The magnification of the intermediate image is about 100 diameters, and the magnification by the projection lens can be varied between 20 and 300 diameters; therefore the total magnification can be controlled over the range between 2,000 and 30,000 diameters. The maximum electronic magnification of the microscope is two or three times less than the greatest useful magnification corresponding to the resolving power of the instrument, the full useful magnification, for reasons that are discussed below, being obtained by additional photographic enlargement. When visual observation of the specimen is required, the final image is allowed to fall on a fluorescent screen. This screen can be raised out of the way to permit the image to impinge upon a photographic plate for a permanent record, or for more detailed examination.

Since electrons will not travel freely through air, the entire electron optical path of the microscope must be under vacuum, that is, at a pressure of about 10^{-4} millimeters Hg. All permanent joints are brazed or soldered so that they are vacuum-tight without the aid of sealing compounds. The demountable joints, such as those between the electron lenses and the microscope chambers, are sealed with Neoprene, and are arranged in such a way that the alignment is maintained by metal-to-metal contacts rather than by the metal-to-plastic contacts. At certain points in the microscope, parts must be movable with respect to one another in order to permit alignment. Such parts are jointed by flexible metal bellows so the adjustments may be made while the microscope is under operating conditions. No greased joints are used in the microscope.

If it were necessary to repump the entire microscope every time a specimen or photographic plate is changed, it would greatly curtail the speed of operation of the instrument. Consequently air locks are provided which permit making these changes without breaking the main vacuum. The air lock for the object chamber (*e*) is shown in figure 3. A handle at the rear of the chamber raises the object from its position over the objective, moves it into the air lock, and closes the latter off from the main chamber of the microscope. A second handle admits air to the lock and opens it so that the object may be removed. When the object is replaced, the second handle closes the air lock, connects it with an auxiliary pump for a preliminary exhaust, and then seals it off. With the first handle, the specimen is moved back into the microscope to its original position.

The photographic chamber, which is shown in figure 4, is arranged with a similar air lock. The photographic plate used with the microscope is about ten by two inches in size. The long plate permits making a number of exposures on the same plate. An adjustable mask governs the width of the pictures.

The microscope pumping system con-

Figure 4. Photographic chamber

sists of a three-stage oil diffusion pump (*l*), in figure 2, which is connected to the main chamber of the instrument through the manifold (*m*). This pump is backed up by a mechanical fore pump. A second auxiliary mechanical pump is used to exhaust the two air lock chambers.

Figure 6. Rear of microscope showing power supply and regulator units

It can be shown that the focal length of a magnetic electron lens depends upon the current through the lens coil and the velocity of the electrons themselves. This means that the high-voltage supply and the lens current sources must be very free from fluctuations. In order to obtain a resolving power of 10^{-7} centimeters it is found that the following stabilities are required:

Over-all microscope voltage	0.015 per cent
Objective current	0.0075 per cent
Projection lens current	0.068 per cent
Condenser lens current	0.1 per cent

The problem of obtaining 60 kv with the required degree of constancy in the small space available is both difficult and interesting. The high-voltage supply, which was designed by A. W. Vance, employs radio-frequency power rather than the conventional 60-cycle power to actuate the step-up transformer unit.[8] This results in a number of advantages. A low-loss resonant coil can be used which occupies only a small volume and requires only a small exciting power. Much smaller condensers can be used for a given allowable amount of ripple. A regulator operating on the low-voltage side of a rectifier is limited in its speed of regulation by the frequency of the power supplied. At radio frequency, this limitation becomes unimportant. Finally, stray fields, which are difficult to shield at 60 cycles, are easily shielded when radio frequency is used. It is, therefore, possible to mount the power supply close to the microscope as an integral part of the unit.

A block diagram of the high-voltage unit is given in figure 5. The basic circuit consists essentially of a high-Q resonant net which presents series resonance to the driving oscillator, and is parallel resonant to the high-voltage output rectifiers. The resonant circuit consists of coil L_0 and the effective lumped capacity C_0, which is made up of the rectifier capacitance and stray capacities. To obtain a given output voltage, the exciting power required from the oscillator, since the load is very small, depends upon the Q of the circuit and the resonant impedance of the high-voltage coil. Great care must be used in the design of the coil and in the selection of operating frequency in order to obtain a high Q and maximum impedance. The actual frequency selected is 32 kilocycles, and the Q of the resonant circuit is about 200. The exciting power required to produce the desired power is about 150 watts, and the maximum load in the neighborhood of 30 watts.

Since the Q of the resonant circuit is high, the driving frequency from the oscillator must be exactly correct if large inefficiencies are to be avoided. In order to maintain the correct driving frequency, the frequency oscillator is controlled by the resonant circuit itself. The output voltage of the power supply is governed by the amplitude of the current from the oscillator. This, in turn, is varied by the screen-grid voltage applied to the oscillator output tubes. By controlling the screen voltage, not only can the output voltage be set at any desired value, but also the constancy of the voltage can be governed.

The rectifier across the resonant circuit is arranged to give voltage doubling. The type of doubler used permits grounding one side of the high-voltage coil, thus permitting the use of a simple resonant circuit rather than a tuned transformer.

Figure 7. Preparation of supporting films for specimens

Figure 8. Micrograph of pseudomonas aeruginosa bacteria. Magnification 14,000 diameters

Figure 9. Micrograph of slightly polymerized vinyl chloride. Magnification 77,000 diameters

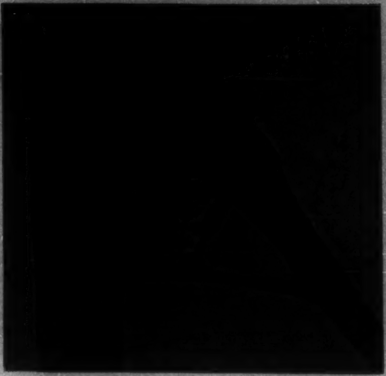

Figure 10 (right). Micrograph of polymerized vinyl chloride. Magnification 100,000 diameters

The high-frequency ripple is eliminated from the high-voltage output by means of a tuned filter. Low-frequency disturbances are removed by comparing a fraction of the output voltage obtained from a special divider with a standard voltage,[4] and controlling the oscillator screens by means of a d-c amplifier. Such a feedback regulator, when certain necessary precautions are effected, is capable of extreme constancy. The measured voltage fluctuation over a period of 30 minutes is less than 0.002 per cent in the actual microscope power supply.

The current supplies for the three lens coils are controlled by very sensitive regulators. These regulators make use of well-known principles, and will not be discussed here.[4] By careful design and the use of a number of special refinements, these current sources have a constancy of better than 0.002 per cent for the objective lens, 0.004 per cent for the projection lens, and 0.02 per cent for the condenser lens.

The complete power supply is assembled in a cabinet which forms the back part of the microscope unit. The lens current sources and the oscillators are located at (*e*) in figure 2. The high-voltage coil, rectifiers, and filters are immersed in the oil tank (*f*). Short, corona-proof leads carry the high voltage to the gun of the microscope. All power supplies are completely interlocked to insure absolute safety, and protective relays are arranged to open the high-voltage circuit in event that vacuum conditions within the microscope are not right. Figure 6 is a photograph of the rear of the instrument with the door to the power-supply section open so that the general arrangement of the equipment can be seen.

The operation of the instrument is simple in the extreme. The operator seated in the observers' position can reach the electrical controls and thus adjust overall voltage, magnification, or focus, while watching the image. In addition, the specimen can be moved in two directions in a horizontal plane, so that any portion of the object may be brought into the field of the microscope. Six ports are provided for viewing the final image, and, in order to permit initial orientation of the specimen, three small windows allow direct observation of the intermediate image.

To record the image photographically, it is only necessary to move the plate into position under the fluorescent screen, and then to raise the screen so that the electron image falls on the plate. The fluorescent screen is designed to serve as the shutter for timing the exposure. It is expedient when making electron micrographs to use as low an electronic magnification as possible, and to obtain the

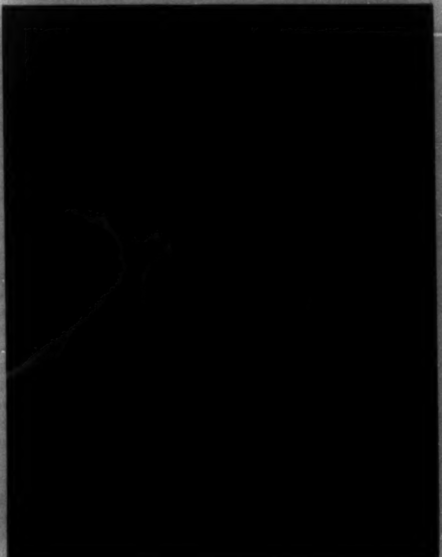

Figure 11. Micrograph of commercial chemical. Magnification 150,000 diameters

Displacement and Diffusion in Fluid-Flow Arc Extinction

JOSEPH SLEPIAN
FELLOW AIEE

Synopsis: The displacement and diffusion theories of arc extinction in flowing fluids are defined and contrasted. The question as to the possibility according to hydrodynamical principles of the formation of the wedge required by the displacement theory is considered and decided in the negative. Photographic evidence is also found to contradict the displacement theory. How turbulence will multiply diffusive effects is considered, and an estimate of 100fold multiplication is given for conditions existing in gas blast breakers. This enhancement of diffusion by turbulence is found to make the diffusion theory adequate for accounting for the circuit interrupting capacities of arcs in gas blast circuit breakers.

I. Introduction

THE important large effect which motion of the circumambient fluid has upon the circuit interrupting ability of an a-c arc has long been known, but there are still widely diverging theories as to how this effect comes about. Slepian,[1] in discussing the influence of gas motion in self-generating gas blast devices such as oil circuit breakers and expulsion fuses stressed the effect of turbulence in causing a more rapid mixing of hot and cold gas volumes, thus speeding the spread of heat, and a more rapid mixing of highly ionized with unionized gas volumes, thus speeding the dilution of the ions into larger volumes. The theory here, then seems to have been that the function of the gas motion is to intensify or enhance diffusive effects, and more particularly, thermal conduction and ion diffusion. This type of theory which makes the powerful arc extinguishing effect of the fluid flow depend entirely upon its creating conditions where diffusive effects are greatly enhanced shall be called in this paper the "diffusion theory".

A radically different theory of the extinguishing effect of the fluid flow was advocated by Prince,[2,3] which shall be called in this paper the "displacement theory". This theory states that at current zero (or perhaps at a moment very near to current zero), the physical continuity of the arc is broken at some obvious geometrical point, by the interposition of a small quantity of *cool, un-ionized*, and *dielectrically completely sound* fluid. From this moment on, the dielectric strength of the arc space is completely given by the dielectric strength of this interposed fluid. The relative velocity of the two ends of this interposed fluid is believed to be one or sometimes two times the mean velocity of the fluid in that neighborhood. Thus the thickness of the interposed fluid grows rapidly, being given by the product, vt, of the fluid velocity and the time. The rate of growth of the total dielectric strength of this interposed fluid in volts per second, will be given by Xv, where X is the intrinsic dielectric strength of the interposed fluid in volts per centimeter, and v is the fluid velocity in centimeters per second. Arc extinction thus is said to depend on whether or not this rate of recovery of dielectric strength of the interposed fluid exceeds the so-called "recovery rate" of the circuit. That is the arc will be extinguished if

$$Xv > \frac{dV}{dt}$$

where $\frac{dV}{dt}$ is the circuit "recovery rate" in volts per second.

Apart from whether the "displacement theory" is correct or not, it has the incontestable advantage that it leads directly to an attractively simple equation, so that the designer or user of a circuit breaker who accepts this theory may have the comforting assurance that the breaker performance has been "calculated". Hap-

---

full useful magnification by photographic enlargement of the plates. In general, a photographic enlargement of six to ten times can be made without bringing out the grain of the emulsion. Therefore, if the total useful magnification required is 100,000 diameters, the electronic magnification will be 10,000 to 16,000. The advantages of this procedure are that it decreases the exposure time, reduces the bombardment to which the object must be submitted, and increases the useful field of view of the microscope.

The specimens themselves are mounted somewhat differently from those used with a light microscope. Glass slides would be completely opaque to electrons; therefore the objects to be examined are mounted on extremely thin cellulose films, supported by a fine wire mesh. The method of preparing one of these supporting films, which are only about 0.000001-centimeter thick, is illustrated in figure 7. The material or particles to be studied are usually suspended in water or some other suitable liquid, and a drop of the suspension is placed on the film. After the liquid has evaporated, the specimen is ready for use.

The utility of this instrument is almost unlimited, and it finds applications in many fields of scientific and industrial research. Two fields, chosen at random, serve to illustrate its value. In bacteriology and biology it opens up new and entirely unexplored realms, for with this microscope microorganisms such as viruses, which cannot even be seen with an optical instrument, can be studied in detail. Figure 8 is a typical micrograph of pseudomonas aeruginosa bacteria. Much of the structure seen in this photograph is well below the resolving power of an ordinary microscope. In physical chemistry it can be used to study colloids, point reactions, the structure of thin films, and even large organic molecules. To illustrate this application, micrographs of slightly polymerized and polymerized vinyl chloride films are shown in figures 9 and 10. The final photograph illustrates a commercial chemical product. Structure of less than 50 angstrom units can be resolved in this micrograph.

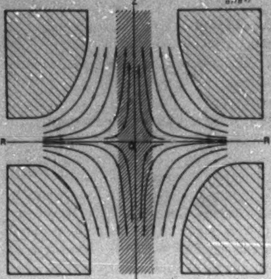

Figure 1. Ideal flow in a double nozzle

pily, however, designers of breakers "calculated" in this way have not dispensed with thoroughgoing high power laboratory tests, so that the performance of such breakers rests on a more solid foundation than the "calculation".

European investigators have advocated both the diffusion and displacement theories. O. Mayr[4] quite definitely makes diffusive effects the dominating factor in determining arc extinction, but Kesselring and Koppelmann[5] principally because they are not able to calculate a sufficiently large interrupting effect on the basis of diffusion, espouse the displacement theory. However, in their calculations which at best can only be regarded as giving orders of magnitude, because of the uncertainty of our present knowledge of the fundamental processes going on in the rapidly changing arc, Kesselring and Koppelmann underestimate completely the great enhancement of diffusive effects arising from even only a moderate degree of turbulence.

Holm, Kirschstein, and Koppelmann[6] speak of the effect of gas motion and its turbulence in increasing the thermal losses from the arc during the current conduction period, but do not take into account the effect of turbulence in increasing ion loss by enhanced diffusion. Also, surprisingly, although they seem to recognize the importance of turbulence during the conduction period, in the "currentless pause" (stromlose pause) near current zero they use for the thermal conductivity and ion diffusion coefficient numbers appropriate to a gas at rest, and overlook the great increase in these quantities arising from the gas motion. Thus they greatly underestimate the voltage interrupting capacity of an arc of small section at current zero.

These last authors also speak of the possibility of a cutting of the physical continuity of the arc, but state at once that such cutting cannot happen, *loc. cit.*, page 84, but that rather a configuration favorable for rapid diffusion occurs where one might naively suggest a cutting. With this exception, none of the references just mentioned question whether accepted hydrodynamical principles will permit the formation of a growing wedge of sound fluid interrupting the continuity of the arc.

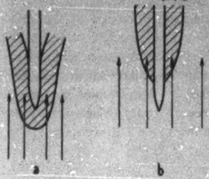

Figure 2 (left). Wedge formation at sharp splitter in ideal fluid

II. Impossibility of Wedge Formation in Interior of Ideal Fluid—Diffusion Absent

To see clearly why hydrodynamical principles forbid the formation of an interrupting wedge, consider the flow of an ideal fluid pictured in figure 1. This portrays a flow corresponding to the double nozzle discussed by Kesselring and Koppelmann. We choose an ideal fluid, that is, one with zero viscosity, because we wish to exclude diffusion effects, and viscosity is a consequence of diffusion, namely the lateral diffusion of molecules from faster moving regions into slower moving regions, and vice versa. For simplicity in calculations let us assume the fluid incompressible. A little thought soon convinces one that compressibility does not alter the conclusions reached.

In figure 1 we have fluid flowing inward radially through a circumferential opening, and axially out along the *Z* axes through a double nozzle. At the time $t=0$, we fix our attention upon the column of fluid shown shaded, which might be the arc configuration near current zero. However, to keep the flow considered simple, let us assume that the shaded column of fluid has the same density as the rest of the fluid, and not a much lower density as in the high temperature arc. We may perhaps regard the shaded column of fluid marked with a nondiffusing ink giving a negligible density change in the fluid.

One might imagine from inspection of the figure, that as the flow proceeds, the shaded column would be broken or cut in two, and that presently the two newly formed ends would be receding from each

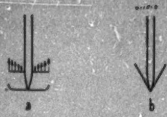

Figure 3. Bending of an arc around a gas-forming splitter

other with twice the axial fluid velocity through the nozzles. However, a little calculation shows that this is not at all the case. In the neighborhood, *O*, of the geometrical center of the figure, the axial velocity is given by

$$v_z = Az \tag{1}$$

where z is the distance along the axis from *O*, and *A* is a constant, and the radial velocity, is given by

$$v_r = \frac{dr}{dt} = -\frac{1}{2}Ar \tag{2}$$

where r is the distance from the central axis. These equations will hold approximately out to distances approaching the nozzle dimensions.

The bounding cylindrical surface of the shaded region will be described by the equation,

$$r = r_0 \tag{3}$$

at $t=0$.

The subsequent motion of this bounding surface will be obtained by integrating equation 2. We obtain at once,

$$r = r_0 e^{-\frac{1}{2}At} \tag{4}$$

The cylindrical surface remains cylindrical, but its radius approaches zero at a constantly diminishing rate. There is no formation of a surface with two nappes; no interrupting wedge appears. The length of this cylindrical column of constantly diminishing radius will be comparable with the nozzle dimensions.

To get some quantitative ideas of the rate of thinning of the cylindrical column, let the axial velocity of the fluid be $3 \cdot 10^4$ centimeters per second at 1 centimeter from *O* then $A = 3 \cdot 10^4$. Then equation 4 becomes

$$r = r_0 e^{-\frac{t}{66.7 \times 10^{-6}}} = r_0 2^{-\frac{t}{45.2 \times 10^{-6}}} \tag{5}$$

We see that the column has its radius halved each 45.2 microseconds, but the radius never becomes actually zero.

If we assume no diffusion takes place, the density of the ink marking the thinning column remains unchanged. Applying the ideas developed here to the arc, we see that pure streaming, without diffusive effects, will thin the arc, but will not change its temperature or ion density, and therefore will not change its dielectric strength per unit length.

III. Enhanced Diffusion Responsible for Interrupting Effectiveness of Axial Flow

The preceding section has made clear that without diffusion (of which thermal conductivity and viscosity are consequences), axial streaming of the fluid as in a double nozzle can have no interrupting effect upon the alternating current arc near current zero. All it can do is to cause the radius of the arc stream to shrink asymptotically to zero, with no change in ion density or temperature of the arc space.

However, it is evident that this effect of the motion of the fluid in reducing the arc diameter can play an important part in increasing greatly the interrupting effect of such diffusive forces as are intrinsically present. The time constant for diffusion from a cylindrical region, that is, for example the time for the ion density to be reduced to one-half, or the time for the temperature to fall to one-half, varies as the square of cylinder diameter. Thus, in the numerical example given in the preceding section, the rate of ion loss, and the rate of cooling will multiply by 4 every 45.2 microseconds, during the interrupting period, due to the reducing arc diameter.

However, this is far from the whole story. As Kesselring and Koppelmann[5] have shown, taking the small arc diameters such as are actually observed at current zero in the double nozzle flow, ordinary diffusion and thermal conduction are still not great enough to account for the observed interrupting effect. The high interrupting capacity comes because there is inevitably a high degree of turbulence in the axial flow through the arc.

In the example discussed in the preceding section and pictured in figure 1, the velocity in the incompressible ideal fluid varies in space according to equations 1 and 2. By Bernouilli's principle, the pressure in the fluid will vary in space according to the equation

$$p_0 = p + \frac{1}{2}\rho(v_z^2 + v_r^2) \qquad (6)$$

where p_0 is the pressure at 0, the point of zero velocity. At each point, the velocity is determined by the fall in pressure to that point, but it should be observed that for a given pressure distribution, the velocity will vary inversely with the square root of the density of the fluid.

But now suppose that the shaded cylinder of figure 1, instead of having the same density as the rest of the fluid, has a density, like that of an arc, only $^1/_{20}$ or less, of the density of the surrounding fluid. The pressure distribution must remain continuous. Hence at any particular distance from O, the velocity in the arc would need to be $\sqrt{20}$ or more times the velocity of the adjacent cool and more dense fluid. There would have to be then a sharp discontinuity in fluid velocity, and enormous shearing stresses at the arc boundary due to viscosity. What happens under such conditions is that the smooth streamline flow portrayed in figure 1, is replaced by an intensely turbulent flow through the arc, the kinetic energy of the turbulence adding itself to the kinetic energy of the average motion to give a total velocity head compatible with Bernouilli's equation 6.

As we shall see in section VI, this high degree of turbulence functions to further greatly increase the rate of cooling and deionization of the arc stream at current zero, and probably fully accounts for large interrupting capacity of the axial flow.

IV. The Cross Blast—Wedge Formation at a Splitter

Compressed air circuit breakers have been recently introduced[7] in which the arc is blown transversely against several splitters made of gas forming material. Let us examine what may happen to an arc column at such a sharp splitter.

Under the influence of the fluid motion, the arc is lapped round the sharp splitter in a thin column as current zero is approached as in figure 2*a*. What does the further motion of the fluid do to this column? Photographic records show that the thickness of this column is too great for simple diffusion or thermal conductivity to account for the high interrupting capacity actually found. Does the moving fluid cause the column to be cut, and introduce between the cut ends a longer and longer path through good dielectric? Or does the fluid motion so enhance diffusive effects that even the relatively thick long column cools and deionizes quickly enough to have a high interrupting capacity?

If the fluid is ideal, with zero viscosity (and therefore also with zero thermal conductivity and zero ion diffusion), the answer is certainly that the arc column is cut as in figure 2*b*, with the recovered dielectric strength equal to that of the path through the introduced fluid between the cut ends of the arc column. The displacement theory then will apply. But

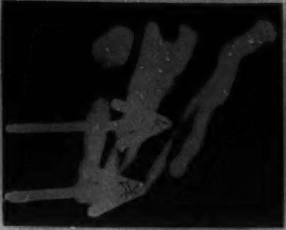

Figure 6. Arc against splitter, by Prince

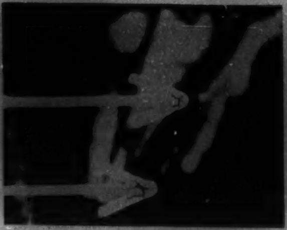

Figure 7. Arc against splitter, $16^2/_3$ microseconds after figure 6

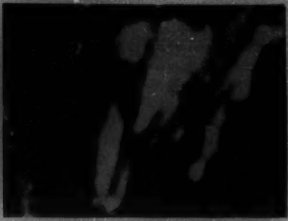

Figure 8. Arc against splitter, $16^2/_3$ microseconds after figure 7

the fluid will need to flow with its full velocity parallel to and right up to the splitter wall.

However, actual fluids cannot flow in this manner. Even with very small viscosity, the fluid velocity next to the splitter wall must be zero. Otherwise infinite shearing stresses would be exerted on the fluid and wall. A layer is formed next to the splitter wall, in which the fluid velocity varies from zero at the wall, to the full streaming velocity away from the wall. In this boundary layer, the shearing stresses arising from viscosity are large compared with the inertial forces.

With homogeneous fluid, the boundary layer starts with zero thickness at the splitter edge, and grows in thickness upstream from the edge. In this first part of the boundary layer, the flow is laminar, but at some point far enough upstream the flow in the boundary layer becomes turbulent, and the boundary layer thickness then increases more rapidly.

For air, at high velocity, and with a well designed splitter, such as an air-foil, the boundary layer a few centimeters upstream is only a few thousandths or a hundredth of a centimeter thick. We might imagine then that figure 2 could be corrected by drawing such a thin boundary layer joining the two receding ends of the cut column. Since so thin a boundary layer would cool and deionize exceedingly rapidly, this correction would not seriously change the conclusions of the displacement theory.

However, in the actual circuit breaker, we do not have a homogeneous fluid flowing past the splitter, but the density of the arc column is only one-twentieth that of the flowing air. We may expect then that the boundary layer will start in a turbulent state from the very beginning at the splitter edge. Still further complicating the situation is that under the heat of the arc, the splitter material gives off gas at a high rate, this gas evolution continuing right through current zero. This gas projected out from the wall will certainly widen the boundary layer enormously, and make it wide even at the beginning of the splitter. But with a wide boundary layer, the displacement theory fails completely since a wedge of fresh fluid interrupting the arc growing with the full streaming velocity of the fluid cannot form. The arrows in figure 3*a* are intended to show by their length the mean velocity distribution in the boundary layer. We fix our attention on the horizontal line just touching the splitter edge, and which we suppose moves with the fluid. This line may represent a bounding surface of an arc column near current zero. A finite time later the line will look as in figure 3*b*. Because of the zero velocity at the splitter surface, the line is bent, but not cut.

V. Photographic Evidence Concerning Displacement Versus Enhanced Diffusion

High-speed motion pictures taken of arcs being extinguished in axial and cross blasts offer valuable evidence for determining whether the displacement or enhanced diffusion theory is correct. J. Biermanns[8] shows pictures taken at 5,000 per second of an arc blown through a single nozzle. Figures 4 and 5 are examples taken from Biermanns' paper. Extinction seems to have taken place after the fourth picture in figure 5. If the displacement theory were correct we would expect to see in the fifth picture a completely dark break in the continuity of the luminous arc, and this break should be at most $200 \cdot 10^{-6}$ second, the time interval between pictures, multiplied by the probable velocity, about $3 \cdot 10^{4}$ cm, or about 6 cm. Actually, in the fifth picture of the lower half of figure 6, there is a length of about this magnitude which is darker than the rest, but it is not completely dark, and also there are in it several splotches which are more intensely luminous. If this darker length does represent the growing wedge introduced into the arc according to the displacement theory, we must conclude that this wedge far from being fresh dielectrically sound fluid, is considerably contaminated by inmixing of ionized and radiating gas from the arc itself. This contamination, which is evidence of considerable turbulence, should be extremely great when the wedge is short, thus making it impossible to speak at all of a short wedge of nearly fresh dielectrically sound fluid. It is only after the "wedge" is of considerable length that it can have decontaminated itself so that it can be regarded as being of dielectrically sound material. This decontamination, however, according to section II can proceed only from diffusion, so that we are driven inevitably to the diffusion theory according to which a considerable length of the arc column finds itself in a condition so favorable for rapid diffusion that it recovers dielectric strength sufficiently rapidly to effect circuit interruption.

Comparison of the upper part of figure 5 with the lower which was obtained from a photographic print with much less contrast, also gives evidence of diffusion much intensified by turbulence. The sharply defined intensely luminous arc column in upper figure 5 is revealed in lower figure 5 as surrounded by less luminous gas which must have diffused rapidly out of the arc column.

Prince[7] has shown some extraordinary pictures taken at 60,000 per second of a circuit interruption by an arc in a cross air blast against fiber splitters. Three of these successive pictures, which are believed by the present author to include the moment of circuit interruption are reproduced here as figures 6, 7, and 8. In figure 6, the arrows introduced by this author point out the two-inch length of arc which he believes to have been responsible for the circuit interruption. This length of arc lies squeezed up against the splitter surface. At the splitter surface itself, the mean velocity of the gas in the arc parallel to the surface must be zero. At the other boundary of the arc, the non-luminous air is moving with very high, probably acoustic velocity. The velocity gradient is then very large in this arc. Also, there is a very sharp change in gas density at the boundary of the arc. Lastly, gas from the decomposing splitter is being projected perpendicularly into the arc column. All these factors must create an intense turbulence, which must so enhance diffusion that these two inches of arc are cooled and deionized extraordinarily rapidly.

In any case, figure 7 shows that after only $16\frac{2}{3}$ microseconds the two inches have lost most of their luminosity, and in figure 8, after another $16\frac{2}{3}$ microseconds the luminosity has almost completely disappeared. If we assume acoustic velocity of $3 \cdot 10^4$ cm per second, the fluid displacement in $16\frac{2}{3}$ microseconds would be only $\frac{1}{2}$ cm. This is very small compared to the two-inch length of arc column which seems to be the first less luminous break to make its appearance in the succession of pictures. Thus these high speed pictures of Prince support strongly the enhanced diffusion theory as against the displacement theory.

VI. Turbulence and Enhanced Diffusion

Appreciation of the fact that fluid motion enhances diffusion is as widespread as the custom of accelerating the sweetening of coffee by stirring with a spoon. Recent developments in the theory of turbulence, however, now make it possible to give a rough numerical measure to this degree of enhancement.

When a sufficiently small dimensioned measuring instrument is used, the velocity at a given point in a steadily streaming fluid is found to be not constant, but to have very rapid variations in magnitude of an apparently random character. Thus figure 9 shows the velocity reading obtained by Dryden[9] in a wind tunnel with a hot wire anemometer made of Wollaston wire, 0.008 mm (0.0003 in.) in diameter. This rapidly varying deviation, u, from the mean velocity U is called the turbulent velocity, and its root mean square with respect to time, $\sqrt{\overline{u^2}}$, is called the intensity of the turbulence. The ratio of the turbulence intensity to the mean velocity in figure 9, according to Dryden is as much as nearly 0.01, even in a wind tunnel where every effort is made to eliminate turbulence as far as possible. In the cases discussed in the previous section the ratio of the turbulence intensity to the mean velocity must be very much greater. One, or an even greater number, would seem to be a not unreasonable figure for this ratio. We may then certainly take 10,000 cm per second as a conservative estimate of the intensity of turbulence in the arc columns placed in rapidly streaming fluids in the examples discussed in the previous sections.

Figure 9. Turbulence in a wind tunnel, by Dryden

Turbulence of wind tunnel, $\sqrt{\overline{u^2}}/U = 0.0085$. Time = 0.4 second approximately. Relative amplification = 64

The turbulence may perhaps be pictured as a large number of small eddies or vortices superimposed on the average smooth motion of the fluid. These eddies are of constantly changing size, and velocities, but in a steady state of flow show a statistical constancy. To reveal the turbulent motion, the velocity measuring instrument must have dimensions small compared to the geometrical dimensions of the individual eddies.

This picture suggests how turbulence may bring about diffusion. A very small portion of the fluid upon which we fix our attention, takes part in the motion of an eddy. A moment later, however, it is part of another eddy, having a different center. It can thus wander from eddy to eddy, off the average flow lines of the fluid. But such motion we call diffusion.

A great similarity will be noted between this picture, and the picture of diffusion in a stationary gas offered by the kinetic theory of gases. According to this kinetic theory, even for a gas at rest, the individual molecules have velocities which are random in direction and magnitude. The mean random speed, c, of the molecules is of the order of acoustic velocity of the gas, or for normal air $3 \cdot 10^4$ cm per second.

The motion of a molecule moving in any particular direction will be arrested and changed into other random directions by collisions with other molecules. Thus the individual molecule will wander about in space in a random manner. This random wandering is molecular diffusion.

The speed with which a particular molecule wanders away from any particular fixed point in space will depend on the average absolute speed of the molecule, c, but it will also depend on the average distance the molecule goes before making a collision which changes the direction of its motion, that is the mean free path λ. The diffusion coefficient for the molecule, according to elementary kinetic theory is given by

$$D_m = \frac{1}{3} c\lambda \qquad (7)$$

In looking for an analogous expression to estimate the diffusion coefficient arising from turbulence, we already have a factor which would seem to correspond to the molecular speed, c, namely the turbulence intensity $\sqrt{\overline{u^2}}$. What will correspond to the mean free path λ? Most plausibly, the average eddy size!

G. I. Taylor[10] has recently shown how from measurements of the turbulent velocity, u, a length may be determined of just this character. Taylor considered the correlation coefficient between the turbulent velocities, u_1 and u_2 at two nearby points in the moving fluid. The correlation coefficient is defined as

$$R = \frac{\overline{u_1 u_2}}{\sqrt{\overline{u_1^2}}\,\sqrt{\overline{u_2^2}}} \qquad (8)$$

The dashes above the functions of time in equation 8 signify that the average with respect to time of the functions must be taken.

It may be shown mathematically that if two functions u_1, u_2, have a correlation coefficient R equal to unity, then the two functions must be completely identical in form, that is $u_1 = ku_2$, where k is a constant. On the other hand, if the two functions are completely unrelated, then u_1 is as likely at any moment to differ in algebraic sign from u_2 as to agree with it, and $\overline{u_1 u_2}$ and therefore R will be zero.

If the two points, 1, 2, being considered stayed always on the same eddy, then $u_1 = ku_2$, and $R = 1$. On the other hand if the points 1, 2, are always on different eddies, then u_1 and u_2 are completely unrelated, and the correlation will be zero, $R = 0$. The actual correlation R for two points, which will generally have a value between 1 and 0, may be regarded as measuring the fraction of the time the two points are on the same eddy.

The correlation coefficient may be directly measured by the use of appropriate electrical circuits used in conjunction with very fine hot wire anemometers. Figure 10 shows the correlation coefficient obtained by Dryden[9] as a function of distance of the second point from the first in turbulence produced in a wind tunnel by screens of different mesh sizes. As might be expected when the two points are very close together, the correlation coefficient is unity, and when they are far apart it is zero. The distance in which the correlation coefficient drops to zero gives a measure of the average eddy size.

Taylor[10] defined a turbulence scale factor

$$L = \int_0^\infty R\,ds \qquad (9)$$

where s is the separation of the two points. L may be regarded as the average eddy size, and should be the analogy of the mean free path λ, in the kinetic theory of molecular diffusion. From figure 10, we see that in the turbulence measured by Dryden, the scale factor is of the same order of magnitude as the mesh sizes of the screens producing the turbulences.

Leaning on the analogy with the kinetic theory of molecular diffusion in gases at rest, and referring to equation 7, we arrive at the strong expectation that the effective diffusion coefficient, D_t, due to the turbulence should be given by

$$D_t = B\sqrt{\overline{u^2}}\,L \qquad (10)$$

where B is a constant not very small compared to unity. The ratio of D_t to D_m may then be expected to be of the order of $\sqrt{\overline{u^2}}L/c\,\lambda$. We have just seen that c is of the order of acoustic velocity, and that in practical gas blast circuit breakers $\sqrt{\overline{u^2}}$ is also of the order of 10^4 cm/second λ, under normal gas conditions is of the order of 10^{-5} cm. What magnitude shall be taken for L?

Referring again to figure 10, which shows that the turbulence scale factor has about the same magnitude as the scale of the physical structure responsible for the turbulence we are led to expect that in the gas blast circuit breaker, L, will be about the same as the dimension of the arc section. Near current zero, in the axial flow breaker, this is about 10^{-1} cm, and for the cross blast breaker, with gas forming splitters, it is considerably larger. We find, then, with respect to order of magnitude,

$$D_t/D_m = B\sqrt{\overline{u^2}}L/{}^1/_3c\lambda$$
$$= 10^4\cdot 10^{-1}/10^4\cdot 10^{-5} = 10^4 \qquad (11)$$

Thus we see that under the conditions occurring in gas blast breakers the intense turbulence brings about an enormous multiplication of the effective diffusion coefficient. Even allowing for all the looseness in dealing only with orders of magnitude, we see that a 100fold enhancement of diffusion effects is not an unreasonable expectation.

This means that all the factors contributing to arc extinction, such as ion diffusion and cooling by thermal conduction are also multiplied 100fold. The difficulty then which Kesselring and Koppelmann[4] experience in adequately accounting for the interrupting capacity on the basis of diffusive effects alone, disappears.

VII. Summary

1. The displacement and diffusion theories of a-c arc extinction in rapidly flowing fluids are contrasted.

2. The formation, in the interior of a streaming perfect fluid, of the wedge required by the displacement theory is shown to be impossible according to accepted hydrodynamical theory.

3. The formation, at the edge of a gas forming splitter in a cross blast, of the wedge required by the displacement theory is shown to be impossible according to accepted hydrodynamical theory.

4. High speed motion pictures of arcs extinguished in gas blasts are shown to contradict the displacement theory and support the diffusion theory.

5. Rough calculations are given which show that the turbulence which may be expected to exist in the extinguishing arc in gas blast breaker, may multiply diffusive effects by 100 or more.

6. This multiplication of diffusive effects is stated to be sufficient to make the diffusion theory adequate for accounting for the high interrupting capacity of gas blast circuit breakers.

System Stability

F. W. GAY
FELLOW AIEE

Synopsis: That the specter of a major system shutdown is prominent in the thoughts of many operators is evidenced by the 1939 symposium, covering methods of modernization of station-switching facilities, and the 1940 symposium, discussing means of restoring service to systems after a major shutdown. In this paper, system and apparatus performances are studied, during the period between the time allotted for the functioning of the high-speed relay protection, and the point where the system becomes so unstable that a major shutdown occurs. With a view to the further improvement of system operation, the paper studies:

1. Phenomena preceding and during instability;
2. Method of lengthening the period between the fault and instability;
3. A local high-speed back-up relay scheme;
4. Means of automatically and quickly stabilizing an unstable system; and
5. In case all of the above fail, progressive isolation of the system by zones selected by degree of low voltage.

THE length of time to reach the critical period of instability for severe types of faults, that is, a three-phase short circuit near a generating center, is relatively short and the three major phenomena which come into play within a few seconds, following persistent low voltage, are as follows:

1. Machines, which have demonstrated in normal operation that their overspeed trip will not operate following the throwing off of full load, have tripped off on overspeed in three to four seconds upon the occurrence of very low voltage. This appears to be due to the combination of high speed, following loss of voltage and hence load, hunting between machines, and abnormal mechanical vibrations produced by the electrical disturbance. A variation in the setting of overspeed trips may be a contributing cause, that is, machines with fast operating governors are speeded up (motorized) by machines with poor speed control. In rare instances, a turbine will trip almost instantly upon the occurrence of an electrical disturbance, apparently indicating that severe mechanical vibration, as a result of this disturbance, is the sole cause.

2. Modern pulverized fuel and oil-fed boilers require a continuous supply of pulverized fuel or oil and air to maintain the flame. Low voltage, persisting for more than a few seconds is very liable to upset the carefully balanced supply of fuel and air and to result in flame extinguishment. The boiler must then be restarted by hand to avoid a possible explosion. Temporary loss of steaming capacity results. Low voltage, persisting a still longer time, may cause circulating pumps and other vital auxiliaries to fail.

3. Generating stations, or even individual machines, may pull out of step and overspeed, resulting in heavy crosscurrents between generators and a further drop in the already low voltage.

Relief from the above conditions may be had as follows:

1. It is believed that a major portion of all generators on a system will be found to have overspeed trips which may have their trip latches forced back into position when running at speeds well over normal. On two modern machines, turning at 3,600 rpm and having overspeed latches, it was found possible to force back the overspeed latch which tripped at 110 per cent upon a reduction to 105.5 per cent and 103 per cent speed respectively. It should be possible, on most machines, to force back the overspeed trip and automatically return the machine to governor operation within a fraction of a minute after the overspeed latch has tripped. On many 3,600-rpm machines, the manufacturer requires that the turbine not be run at speed without steam flow for much more than 60 seconds.

2. Where switching facilities permit, essential auxiliaries may have their transformer circuits closely connected to one of the generators which may be tripped from the bus during periods of persistent low voltage, while other parallel sources of auxiliary power are simultaneously disconnected so that this generator will automatically become a house generator during the period of persistent low voltage. Essential auxiliary electric motors, serving powdered fuel boilers, should be of ample size and of high pull-out torque. Such motors should be capable of maintaining satisfactory operation down to 60 per cent voltage. An alternate method is to provide relays operating to clear the station bus after low voltage (below 60 per cent normal) has persisted for several seconds. Clearing a station bus may involve resynchronizing after the disturbance has passed and in such a case may involve a temporary loss of load. Auxiliary power transformers must be so connected that this load is not dropped by the automatic withdrawal from service of any single bus.

3. It is becoming generally recognized that, if low voltage persists on a system for much more than two seconds, it is necessary to split up the system into a number of parts so that trouble on one part of the system will not involve the others. This splitting up of a system leads to certain consequences which must be cared for by the operation of the system continuously in preparation for such a split-up; otherwise, some of the parts will have an excess of generating capacity while other parts will be deficient in generating capacity. That particular section of the system, on which the disturbance originated, may be short of generator capacity following the disturbance. It may, therefore, be necessary to drop load temporarily, either manually or automatically. Such reduction in load can probably best be accomplished by automatically reversing the normal function of feeder-voltage regulators and load-ratio control transformers so that, with a reduction of frequency below approximately 58 cycles, there will be a reduction in service voltage to the limit of this regulating equipment's capacity to buck down voltage. This low voltage will be maintained until normal frequency is closely approached.

Whenever a careful study is made following a system disturbance, it is found that communication facilities, which are adequate for normal operation, are inadequate to permit quick restoration of service following the disturbance. It is believed that eventually it may be necessary to install an entirely different type of communication system if it is desired to handle emergencies efficiently. One such system is suggested as follows:

The head operator at the time of the disturbance shall act as a broadcaster giving orders only, and his broadcast shall be audible to all parties who may have an interest in the orders given. His lieutenants will receive information from the field and set up this information in the form of a load dispatcher's board so that the head operator can visually note the actual instant condition of the system. The head operator's orders will carry to every generating station and switching station operator simultaneously and will include, at least, the turbine room operator, the boiler room operator, and the pump room operator in the generating stations so that each of these men will instantly know when their equipment is, or is about to be called on for increased effort. Any company executive or engineer can be plugged into this circuit and can follow the course of the trouble and the restoration of normal conditions.

Twenty important generators in the Public Service Electric and Gas Company system are, or soon will be, equipped with field adjusters. These field adjusters are inoperative during normal conditions, allowing machine-field strengths to be maintained by hand operation at or above stable values, and allowing reactive volt-amperes as well as watts to be allocated by the load dispatcher. Upon the occurrence of low voltage from any cause, these field adjusters operate instantly to add approximately one-third of normal field current to the field of each generator. Upon the return of normal conditions, the fields are automatically returned to their predisturbance value. The amount

Paper 41-49, recommended by the AIEE committee on power generation and presented at the AIEE winter convention, Philadelphia, Pa., January 27–31, 1941. Manuscript submitted November 19, 1940; made available for preprinting December 11, 1940.

F. W. GAY is assistant engineer for the Public Service Electric and Gas Company, Newark, N. J.

1. For all numbered references, see list at end of paper.

of field current added to each generator is chosen so that no injury should result to any field, even if the high-field current is maintained for many minutes. An alarm warns the operator of high-field current and a volt-ampere (ohm) chart indicates meter readings which must not be exceeded.

Persistent low voltage may so reduce the pull-out torque of a generator that it is unable to transmit to the connected low-voltage system the entire output of its connected turbine which is being supplied with a full quota of steam. The unit will speed up until the governor reduces the steam supply to balance the reduced load and the generator will then continue to run out of step as an asynchronous generator. If the unit is equipped with a field adjuster, it should not trip on overspeed.

The Public Service Electric and Gas Company are equipping five turbine-generators with resynchronizing governors which it is hoped, will overcome this difficulty. Associated with each of these governors is an out-of-step relay. This relay determines an out-of-step condition by reason of the simultaneous occurrence of heavy current and pulsating kilowatts. Upon the occurrence of such phenomena, the relays proceed to close the steam valve and this closing operation continues until the out-of-step relay determines that the generator has resynchronized. (This relay does not alter the setting of the governor, but closes the steam valve against the governor.) When the relay determines that the generator has resynchronized, it returns the unit to the governor by backing off slowly so that the rate of steam supply is changed relatively slowly.

The amount of time used to reload the turbine is proportional to the amount of time taken to resynchronize, that is, the rate of change of load is constant.

Instability is a function of voltage loss. It follows quickly on the heels of a severe voltage drop and more slowly for lesser voltage drops. The following is Mr. Dean's conclusion as stated at last winter's convention, and is a good summation of experience in this respect:

> "It is interesting to note that the index upon which the necessity for emergency switching turns is the voltmeter reading. It has been found from experience that under fault condition, the behavior of current indicating devices is often so erratic as to make them undependable *and that persisting low voltage is about the only reliable criterion.*"

Figures 1 and 2 illustrate a suggested method of back-up relaying for a utility system, based entirely on low voltage. In figure 1, curve *T* shows the characteristics of a simple timing relay which operates to close its trip contacts for a voltage on any phase to ground below approximately 60 per cent of normal and its associated timer closes the trip contacts after an elapsed time of 32 cycles.

Curves *A* and *B* show the characteristics of timing relays which comprise a voltage element on each phase, operating to close the contacts of a timing element on that phase, for phase-to-ground voltage on any phase below a desired minimum. The timing element comprises a watt-hour meter and a rectifier operating across a resistance to normally charge a battery through this watt-hour meter.

A battery, allocated to each phase, is continuously charged from phase-to-ground voltage on that phase through a step-down transformer and full-wave rectifier. A watt-hour meter in this battery charging circuit is connected to operate in reverse for normal charging. A high-speed register on this watt-hour meter turns in reverse against a stop. For phase-to-ground voltages below a desired critical value, the battery discharges through the resistor and at a rate proportional to the drop in voltage below the desired critical value. During the battery-discharge period, the watt-hour meter turns its high-speed register to close the tripping contacts. The rate of closure is proportional to the drop in voltage below the desired critical value.

The multitrip relay opens the main battery-discharge circuit through the potentiometer resistance of the timing relay and the timing relay slowly resets. This circuit is also held open by the voltage element that operates the timing element described above. The reclosing of this circuit follows the reclosing of the multitrip relay only after the re-energizing of the cleared circuit.

For a meter adjusted according to curve *A*, the transformer and resistance taps are chosen so that the battery is discharging for phase-to-ground voltages below 40 per cent of normal and, when adjusted according to curve *B*, the battery is discharging for voltages below 80 per cent of normal.

A suggested use of these relays is illustrated in figure 2 wherein a system, *Y*, is connected to the *NY* bus of station *N*, having short-circuit capacity on the bus *NY* of 1,000,000 kva with system *Y* alone connected; that is, a per-unit reactance for system *Y* of ten per cent, based on 100,000-kva unit. The bus *NY* is shown connected to the red and blue busses of station *N* by transformers *T*-5 and *T*-6. These transformers are of the double-wound secondary type and have an equivalent primary negative reactance of minus 15 per cent (per unit of 100,000 kva) and an individual secondary reactance of plus 60 per cent. One of the secondaries of each transformer is shown connected to the red *N* bus and the other connected to the blue *N* bus. Additional stations *O*, *P*, and *Q* are shown with *N* and each have a red and blue bus. Load on each red bus is carried by transformers such as *NRT*, *ORT*, etc., each feeding a low-voltage load bus, *L*-1, and load on each blue bus is carried by trans-

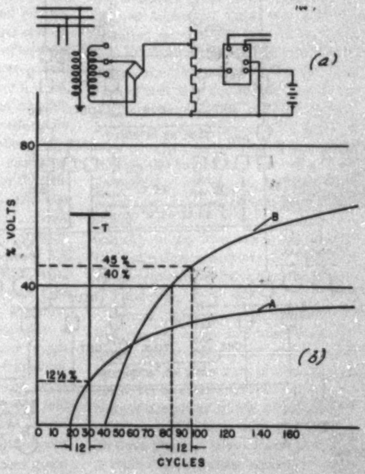

Figure 1a. Diagram of timing element in suggested relay scheme b. voltage-time curves

Curve *A*—Timing element set for 20 cycles (maximum closing speed); range adjusted for operation between zero and 40 per cent volts

Curve *B*—Timing element set for 40 cycles (maximum closing speed); range adjusted for operation between zero and 80 per cent volts formers such as *NBT*, *OBT*, etc., each feeding a low-voltage load bus, *L*-2. The *L*-1 bus is shown connected to the red bus of each station through a transformer having a per-unit reactance of 20 per cent and to a tie bus in common with *L*-2 through 20 per cent reactors. The *L*-2 low-voltage bus is similarly connected to the blue bus and the tie bus. At stations *P* and *Q* two 100,000-kw generators (125,000 kva) are shown, each connected to the red and blue bus through a two-winding secondary transformer having equivalent negative primary reactance of 15 per cent, and a secondary winding reactance of 60 per cent for each winding alone. One secondary of each transformer is shown connected to the red bus and the other secondary to the blue bus. The arrangement shown is identical at station *P* and at station *Q*.

If, now, it is assumed that a three-phase short circuit occurs on the terminals of the power transformer connecting the high-voltage blue bus to the *L*-2 low-voltage bus at station *P* (short-circuit *X*, figure 2) and further, that the relays on this short-circuited transformer bank fail to operate, then a three-phase short circuit will remain at *X* on the blue bus *P* until the *PBT* transformer breaker is opened. (This fault will also remain on low-voltage load bus *L*-2.) The short circuit will, in effect, be a bus short circuit. To this bus, as well as to all other busses, is shown connected a relay of the *A* type, figure 1. With zero voltage on the blue bus at station *P*, the type *A* relay battery will discharge its maximum current through the current coils of the wattmeter-relay element and the high-speed register will turn at maximum speed to close the tripping contacts. As shown on curve *A*, figure 1, these contacts will be closed at approximately 20 cycles after the short circuit occurs, and since the high-voltage breaker on the transformer feeding the *L*-2 low-voltage bus has not operated, all high-voltage breakers connected to the *P* bus will be tripped and the *P* blue bus will be killed within the next 12 cycles. If pilot wire or carrier current is available, the breakers at both ends of lines leaving the blue bus at station *P* may and should be tripped. Voltage-timing relays *T* are shown for the reactor tie busses connecting load busses *L*-1 and *L*-2 at each station. With a short circuit at *X*, figure 2, as shown, the voltage on the tie-reactor busses at stations *N*, *O*, *P*, and *Q* may be less than 60 per cent normal and, if so, these relays start functioning to trip the *L*-1 reactor breakers so that the red and blue busses at stations *N*, *O*, *P*, and *Q* may not be connected through the low-voltage reactor busses. With a short circuit at *X*, as shown, the blue bus at *P* will be removed from circuit before relays *T* operate and only the *T* relay at station *P* will function, due to the fault on its connected transformer bank.

A study of curve *A* will show that, for the arrangement shown, if blue busses at stations *O* and *Q* have a voltage in excess of 12.5 per cent of normal, there will be no danger of the type *A* relays on these busses beating the type *A* relays on the *P* bus. (See dotted lines in figure 1.) With the arrangement as shown, the voltage on the red bus during the short at

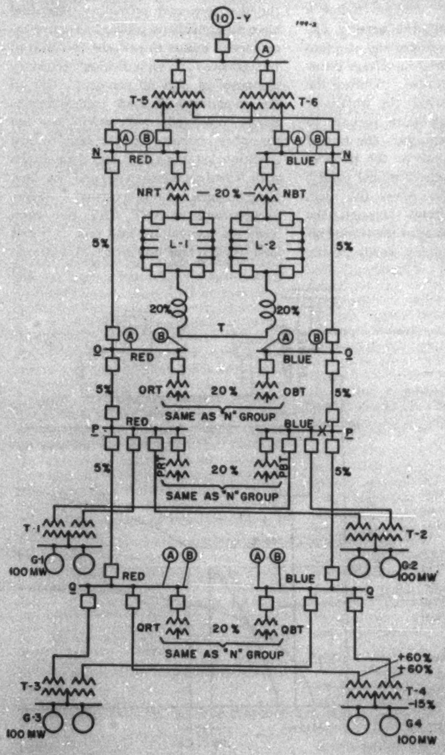

Figure 2. System layout

Employing three-winding transformers, each having a per-unit through impedance of 15 per cent (100,000-kva unit) and minus 15 per cent equivalent negative primary impedance, i.e., 45 per cent impedance through one high-voltage winding

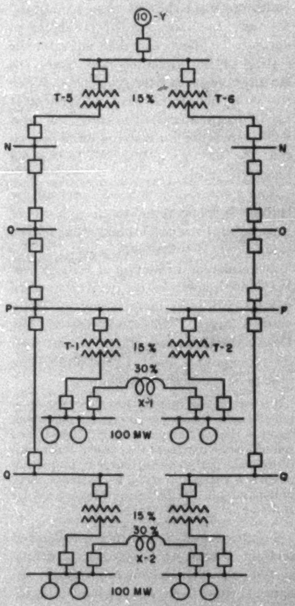

Figure 3. System layout

Similar to figure 2 but employing two-winding transformers each having a per-unit through impedance of 15 per cent (100,000-kva unit)

X will be over 100 per cent and on the blue bus at stations *O* and *Q* there will be a safe margin of voltage over the 12.5 per cent minimum required. The only load that will be lost will be that of the *L*-2 bus, connected to the faulted transformer bank. This bus may be reenergized immediately through the reactor circuits. A short circuit on any high-voltage bus should be cleared by this back-up relay scheme without danger of killing any adjacent bus. Curves *A* and *B* show that, as voltages, during a fault, become higher, the selectivity improves.

The use of relays with a *B* setting are required for protection against persistent low voltage originating outside the high-voltage circuit of the system under consideration as, for instance, trouble on the interconnected system *Y*. If the trouble is sufficiently serious to endanger service on the red and blue bus, the *B* relays at station *N* will function and are connected to trip the oil-circuit breakers of transformers *T*-5 and *T*-6. Again, if the generators or turbines at, for instance, station *Q*, should be in serious trouble, the *B* relays at station *Q* will function to open the output breakers of these generators.

No brief is held for the operating time used in this discussion except that the operating times closely approach the minimum. Longer times will obviously give greater selectivity.

The advantages of a relay scheme similar to the above are as follows:

1. Any generating station bus which has a voltage on it sufficiently low to cause hazard to auxiliary power-station equipment will be removed from service by the back-up relays in a period so short that the functioning of the auxiliary power equipment will not be seriously disturbed.

Note: With this system, auxiliary power transformers must be connected to generator circuits before these circuits reach the station busses, since station busses may be automatically killed in case of a bus fault.

2. A bus at any generating station will be removed from service so quickly that there will be no danger of unloading generators with consequent tripping of overspeed relays and temporary loss of capacity on the system.

3. The low voltage will exist for so short a time that system stability will not be in danger.

Figure 3 differs from figure 2, described above, in showing a more usual transformer arrangement at generating stations *P* and *Q* and interconnecting station *N*. All load circuits *L*-1 and *L*-2 are omitted in figure 3 in the interest of simplicity, as are the red and blue designations. A 100,000-kw (0.8 power factor) generator is shown connected directly to the primary of each of two 125,000-kva transformer banks, *T*-1, *T*-2, *T*-3, and *T*-4 and the transformer primaries at each station, as at *P* and *Q*, are shown connected together through reactors having a per-unit value of 30 per cent (100,000-kva unit). The six transformers, *T*-1, *T*-2, *T*-3, *T*-4, *T*-5, and *T*-6 in figure 2 and in figure 3, are shown to have a straight through reactance to balanced loads of 15 per cent; however, the two-winding transformers shown in figure 2 have an equivalent negative primary reactance of minus 15 per cent and a positive reactance of 60 per cent for each of the high-voltage windings singly so that the reactance from any individual generator to either the red or the blue bus will be 45 per cent for the transformer and, adding the generator subtransient reactance of 10 per cent, 55 per cent total to an individual bus. For balanced loading, the reactance from an individual generator to both busses will be 15 per cent for the transformer plus 10 per cent for the generator, or a total of 25 per cent, and will be the same for both figures 2 and 3. If, in figures 2 and 3, a badly unbalanced condition is considered, that is, 60 per cent load on each of the blue busses against 40 per cent load on each of the red busses as shown, and the generators are loaded to capacity and there is no interconnection load, we find that the total load on the blue bus will be 240 mw and 180 mvar (300 mva) and on the red bus 160 mw and 120 mvar (200 mva). Each transformer shown in figure 2 will be equally loaded, that is, it will have 125 mva on its primary winding and 75 mva on one secondary winding and 50 mva on the other secondary winding. The total loss in each transformer in figure 2 will be approximately 102 per cent of normal, indicating that a small amount of additional copper will have to be added for both high-voltage windings above that required for a balanced load condition. In contrast, in figure 3 it is seen that the two transformers connected to the blue bus must take the maximum load, in both their primary and secondary windings, that is, the transformers will carry 120 per cent of the normal generator rating and will have 144 per cent load loss. The transformers in figure 3 must, therefore, have a continuous-carrying capacity of 150,000 kva per bank. In other words, the single-winding secondary transformers, shown in figure 3, must be something more than 15 per cent larger than the double-winding secondary transformers shown in figure 2. Furthermore, with the instantaneous reactances given, should there be a fault at *X*, as shown on the blue bus for station *P*, the voltage of the generator connected to transformer *T*-2 will be approximately 82 per cent at the instant of fault, while the corresponding voltage at generator terminals in figure 3 will be approximately 63 per cent.

Assuming that all generators are of the modern type, equipped with field adjusters and having a sufficiently high-exciter ceiling voltage to maintain approximately 200,000 kva per generator through the fault, the sustained voltage, with the arrangement shown in figure 2, will be approximately 90 per cent for each of the generators connected to the red and blue bus in station *P*, and 48 per cent for the generator connected to the blue bus in the arrangement shown in figure 3. Furthermore, since the blue bus at station *P* is short-circuited, synchronizing power for generator *G*-2 is through reactor *X*-1 to generator *G*-1 only. It is obvious that generator *G*-2, shown in figure 3, will fall out of step and run above synchronism in the assumed case of failure, that is, relays fail to clear the faulted transformer bank *PBT*, feeding load bus *L*-2 so that the blue bus at station *P* remains short-circuited.

In figure 2, both generators *G*-1 and *G*-2 are equally affected by the fault at *X* and also both generators are connected to the red bus and will not pull out with respect to each other or be unloaded and run over speed. Furthermore, the voltage of the red bus will be over 100 per cent of normal and there will be a powerful synchronizing tie to generator *G*-3 and *G*-4 at station *Q* over the line connecting the red busses at these two stations. Phantom current will flow through the line connecting the blue bus at station *P* with the blue bus at station *Q*. This current will flow due to the mutual inductance between the two high-voltage windings of the transformers *T*-1 and *T*-2. This phantom current will flow directly through the faulted blue bus but not into the fault and will serve to maintain a low impedance between generators *G*-1 and *G*-2 on the one hand, and generators *G*-3 and *G*-4 on the other hand, and between the individual generators *G*-1 and *G*-2 and between the individual generators *G*-3 and *G*-4.

Several years ago, a small model system was set up to determine if the impedance between two machines connected by two parallel transmission circuits could be maintained substantially constant while either of the connecting circuits were simultaneously grounded on all three phases. It was found that, with a relatively enormous equivalent nega-

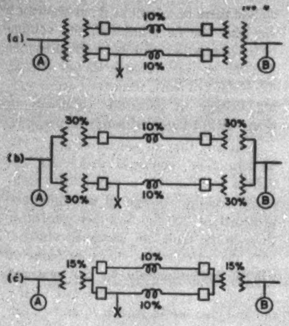

Figure 4

(a)—Simple two-circuit transmission system employing terminal transformers, each having two separately insulated high-voltage windings. Each transmission circuit served by an individual high-voltage winding at each end

(b)—Same as (a) above but each transmission circuit having its own transformer at each end

(c)—Same as (a) above but a single transformer at either end serving both transmission circuits at that end

tive primary impedance in the transformers at both ends of the lines, either connecting line could be short-circuited and the voltage on the nonshort-circuited line would be instantly doubled. The power would flow over the nonfaulted line at double voltage and a phantom power current of substantially equal value flowed over the short-circuited line but did not enter the short circuit.

As the equivalent primary negative impedance of the transformers at both ends of a dual circuit transmission is reduced by design from a relatively enormous value to zero, the effect of a single-line short circuit on the through impedance will be found to change, having substantially no effect for very high negative and double the impedance for no negative.

The value of equivalent-negative primary impedance in reducing fault currents has been well covered in the technical press but the value of such negative impedance in maintaining a stable system seems to have been neglected.

In order to better assure the reliability of large capacity, closely coupled systems, it is believed that operators and manufacturers must find some solution to the factors causing instability outlined in this paper. While the experiences described cover those of one system only and the remedies suggested have had very limited or no field trial, it is hoped that after further development they will prove of substantial value.

Appendix

A two-circuit transmission system was set up on the circuit analyzer to determine the characteristics of a double-wound high-voltage transformer bank having various amounts of equivalent primary negative impedance.

Figure 4 (*a*) is a one-line diagram showing a hypothetical system *A* having infinite capacity connected to a like system *B* by a transmission circuit comprising two transmission lines, each having ten per cent reactance (100,000-kva unit) and being serviced by a transformer at each end, having a single low-voltage winding and two high-voltage windings. Each transmission line is served at each end by an individual high-voltage winding.

Figure 4 (*b*) shows a somewhat similar circuit connecting the two systems *A* and *B*. In this arrangement individual transformers are used in each transmission circuit, each transformer having twice the through impedance of the transformer shown in (*a*) above, that is 30 per cent.

Figure 4 (*c*) shows the same two systems, *A* and *B*, connected through individual transformers to the same two circuits. It is obvious that in normal operation, the performance of the three systems, *a*, *b*, and *c* will be identical, since the through reactances are the same and resistances are neglected.

If a three-phase fault is applied at *X* in each of these systems, it will not be possible to transmit any power between the system *A* and the system *B* with the arrangement shown at (*c*), while with the arrangement (*b*) the power transmitted between system *A* and system *B*, with the three-phase fault existing, will be only one-half the amount that may be transmitted without the fault. (The current flowing from systems *A* and *B* into the fault is of no consequence since these systems are assumed to have infinite capacity.)

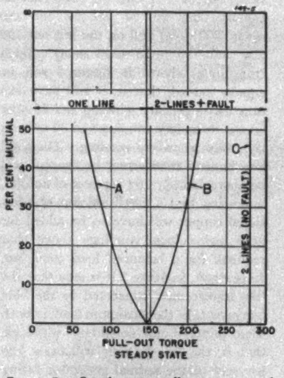

Figure 5. Steady-state pull-out torque of system shown in figure 4a

(a)—Variation of steady-state pull-out torque with per cent mutual for a single line in circuit, i.e., the faulted line cleared at both ends

(b)—Variation of steady-state pull-out torque with per cent mutual for two-line operation and a three-phase fault on one line at *X*

(c)—Variation of steady-state pull-out torque with per cent mutual for two-line operation

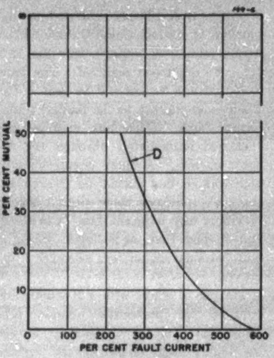

Figure 6. Variation of fault current with per cent mutual

In arrangement (*a*), if the equivalent negative primary impedance (per cent mutual) in the transformers is a maximum by design, then the current that will flow into fault *X* will be negligible, and the transmitting characteristics of the circuit shown in (*a*) will be the same whether the three-phase fault at *X* is present or clear. If the fault is on, the voltage on the nonfaulted line will be 200 per cent. The current flowing in the faulted line will be identical to that flowing in the unfaulted line. This current is called a phantom current and is induced in the faulted line by the mutual impedance in the transformer circuits. As the mutual impedance is diminished, the volts on the sound line during the fault will diminish and the phantom current in the faulted line diminishes.

Figure 5 shows the characteristics of circuit (*a*). The steady state pull-out torque in per-unit (100,000-kw unit) will be approximately 280 per cent, with both lines in circuit and without a fault. This pull-out torque will be a constant, regardless of the amount of equivalent primary negative impedance (per cent mutual) built into the terminal transformers, so long as there is no fault on either transmission circuit. If however, there is a fault on one circuit, the steady-state pull-out torque is shown by curve *B*. This pull-out torque will reduce with a reduction in equivalent negative primary impedance and for zero negative the circuit is the equivalent of (*b*), and the steady state pull-out torque will, of course, be one-half of what it is with an unfaulted line. If now the faulted circuit is opened at both ends to clear the fault, the transmission will be left with a single circuit and

The Water-Cooled Steel-Tank Rectifier Corrosion Problem

EMIL J. REMSCHEID
MEMBER AIEE

Synopsis: The first mercury-arc rectifiers utilized glass tubes and consequently the physical size and electrical capacity was limited. The efforts to increase the available output led to the development of water-cooled steel-tank vacuum chambers after many years of research and the solution of many problems. This paper is primarily concerned with the solution of the problem presented by corrosion. Corrosion is essentially the returning of a metal to its original state and the problem consists in finding a means to retard the return sufficiently so that corrosion will not be a limiting factor in the life of rectifiers.

Analysis of the problem indicates that pitting corrosion causes the greater damage and is largely a function of the character and condition of the metal, the quantity of electricity passing, and also that it is self-propagative. The rate of corrosion is affected by the temperature of the cooling water, the chemical constituency of the water, and potential differences between points on the surface of the rectifier tank.

The first efforts in the solution of the corrosion problems were directed toward finding a protective coating to isolate the steel tank from the cooling water. Various paints, varnishes and lacquers, and enamels were investigated, as well as sprayed metal, but were not found satisfactory. Chemical treatment of the water was then investigated and sodium chromate found to give excellent results. The action of this chemical is reviewed and both laboratory and field evidence of its effectiveness submitted, followed by a discussion of the various factors to be considered in the application of this chemical to prevent corrosion.

Introduction

WITH few exceptions, all machines for the generation and conversion of electrical energy have been mechanical in nature. During the early part of the present century, Cooper-Hewitt and Steinmetz presented to the electrical world a conversion unit for transforming alternating current to direct current which was nonmechanical, but electronic in nature. This conversion unit known to us as the glass-bulb mercury-arc rectifier, has since its introduction won wide acclaim as an efficient, practical converter. Because of the fragility of glass, the physical size and current rating of the mercury-in-glass rectifier has been essentially limited. The desirable features of this particular type of converter are as follows:

(*a*). High operating efficiency
(*b*). Silent operation
(*c*). Absence of moving parts
(*d*). Comparatively long life

Studies were soon begun to increase the current rating, operating potential, and naturally its physical size. As it was impractical to increase the physical size of the mercury-in-glass rectifiers, a substitute for glass was sought. This investigation which was carried on by several groups, both in the United States and abroad, resulted in the adoption of the steel-tank vacuum chamber. Subsequent investigations indicated that by surrounding the steel vacuum chamber with a water jacket, the heat losses[1] could be effectively removed and the rating of the rectifier considerably increased. This transition from the glass to steel vacuum chamber and the increase in rectifier rating required several years of research and necessitated the solution of many problems before this new rectifier was available for service in the field. It is the purpose of this paper to explain the steps taken to overcome one of these problems, namely the corrosion problem, which became evident during the early days of the water-cooled steel-tank rectifier field performance. While this subject does not pertain to the phenomena of rectification, nevertheless, its immediate solution was necessary in order to give the assurance that the life of the water-cooled steel tank rectifier would not be limited by corrosion. This assurance would make its future manufacture and application economically justifiable.

The Corrosion Problem

Water when available in sufficient quantities is one of the most practical and economical mediums for controlling the temperature of machines. Likewise, iron is one of the most practical and economical metals for the fabrication of machines.

The application of water in contact with iron presents to the manufacturer and operator of electrical apparatus, the so-called "corrosion problem." This problem presents itself in varying degrees, occasionally of no consequence, and then again if not retarded, considerable damage results. This damage may appear as loss of good will, interrupted service, or expensive repairs. The performance or the life of electrical or mechanical apparatus of the present day should not be determined by the corroding away of the water-cooled iron parts.

Because of the many different theories regarding its nature, corrosion is generally studied from an academic point of view. When one studies the many possible causes for the corrosion of iron, one can readily appreciate why the early students of the corrosion problem, asked themselves, why ferrous metals survive corrosion at all.

Corrosion of metals is essentially the reverse of smelting, or in other words, corrosion is the returning of a metal to its original ore state. As corrosion in the theoretical sense cannot be entirely stopped, nevertheless, we must find means to retard it sufficiently so that corrosion will in no way be a factor to impair the performance or limit the expected life of apparatus, especially where water is used as a coolant.

The temperature of steel-tank rectifiers of early manufacture were controlled by tap water cooling, using whatever water was available for the purpose. In locations where water from city mains was not available, wells were provided near the station. As the quantity of water available was the criterion rather than the quality, many of the waters corrosive in nature were used as a coolant. The more corrosive waters attacked the iron parts of the rectifier and subsequently advanced stages of corrosion

---

with this single circuit, the one-line steady state pull-out torque will vary inversely as the negative impedance (per cent mutual), diminishing with an increase in such impedance in accordance with curve *A*. The current in the fault *X* will vary with equivalent primary negative impedance having approximately 580 per cent value for zero negative impedance (per cent mutual), and diminishing along the curve *D* to have a zero value for an infinite negative impedance (figure 6).

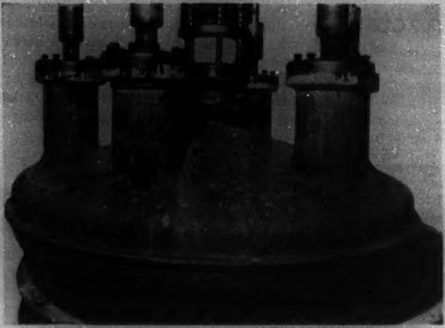

Figure 1. Tubercles on mercury-arc-rectifier vacuum chamber

were noted, some instances resulting in vacuum leaks in the rectifier or water leaks in the water jacket.

The Corrosion Study

Examination of the corroded parts of various rectifiers indicated that pitting corrosion rather than the so-called general corrosion was causing the greater damage. In "general corrosion" the anodic and cathodic areas which characterize all corrosion attack by water on iron are evenly distributed and of such fine grain, so to speak, that the net attack is fairly uniform and so slow as to be unimportant. This effect is largely a function of the character and condition of the metal. No way is known to insure that corrosion attack shall be confined to this type. "Pitting corrosion" occurs when positive anodic areas are set up surrounded by relatively large cathodic areas. This may result from patches of mill scale or other foreign matter or from inhomogeneity of the metal, as at welded junctions. It is the usual situation in fabricated structures since anodic areas are essentially areas of oxygen starvation. The resultant pitting is self-promoting: The condition once established tends to become worse. Figure 1 shows the presence of tubercles of iron oxide resulting primarily from pitting corrosion. These tubercles are small mounds which grow in size in proportion to the quantity of electricity passing between the covered portion acting as anode and the surrounding metallic surface acting as cathode, and are generally found at welded junctions, breaks in mill scale or at a point where a foreign substance is attached to the iron. From within the tubercle or pit anodically produced iron salts diffusing outward meet a relatively alkaline water from the cathodic area whereby the iron is precipitated forming mounds of black magnetic iron oxide, which further obstruct the access of oxygen. Being loose and not adherent, they do not constitute a protective film. Deposits of this nature, when not removed and the pits repaired or thoroughly cleaned, ultimately cause perforation of the water jacket. Tubercles shown in figure 1, occurred at the hottest point and on a welded surface. Figure 2 shows the surface of a rectifier water jacket before cleaning. Many tubercles and much water sediment is evident, with a fertile field for corrosion. Figure 3 shows the cleaned surface, with the pits in the iron jacket plainly visible. It is readily seen that such disintegration if allowed to continue will reduce the active life of apparatus. The application of sodium chromate even in this advanced stage will stop corrosion and make corrosion no longer the limiting factor of the machine's life. This preliminary study taking into consideration the several variables all conducive to corrosion, placed the rectifier corrosion problem in a category of its own. These variables may be enumerated as follows:

The rectifier water temperatures are variable, often ranging from tap water temperature to boiling water temperature.

The waters in different localities also differ in chemical composition.

During operation the steel tank rectifier has inherent differences in potential between points on its surface.

The rate at which corrosion occurs, is greatly increased with increase in temperature. This is due mainly to the fact that both the electrical conductivity of an electrolyte and the rate of chemical action increase with temperature. It is for this reason that water-cooled parts of rectifiers operating in excess of 50 degrees centigrade corrode at a considerably higher rate than those operating at lower temperatures.

It is of interest to note the differences in chemical constituents of the various waters used as rectifier coolants throughout the United States. These waters are classed as lake waters, river waters, mountain spring waters, and local well waters. The following table shows the extremes, in parts per million (ppm) of the constituents in these various waters:

	Maximum	Minimum
Total hardness ($CaCO_3$)	370	3
Total dissolved solids	353	19
Silicon (Si)	39	1.6
Iron (Fe)	1.4	0
Calcium (Ca)	107	0.8
Magnesium (Mg)	25	0.2
Sodium (Na) Potassium (K)	74	1.2
Bicarbonate (HCO_3)	289	7.3
Sulphate (SO_4)	120	1.7
Chloride (Cl)	44	0.7
Nitrate (NO_3)	25	0

The excess of some of the constituents listed in the above table are harmless, while the excess and combination of others provide fertile grounds for corrosion.

The presence of calcium carbonate is nearly universal. Where it is not associated with an excess of free carbonic acid it tends to precipitate along with the rust on iron surfaces forming a dense scale which resists further corrosive attack. In fortunate cases, the accumulation of this scale is so slow that it does not cause troublesome interference with heat transfer. Where, on the other hand, an excess of free carbonic acid is present deposition of calcium carbonate is prevented and the water becomes "aggressive" toward iron.

The first step in the search for a remedy of the rectifier cooling system-corrosion problem was naturally to find a protective coating which would perfectly isolate the iron parts of the rectifier from the water of the cooling system and thus prevent corrosion.[3] Asphaltum, metallic and metallic oxide paints recommended for their corrosive-preventive merits were studied. Varnishes and various lacquers were investigated. The corrosion-resisting properties of sprayed molten metals and their combinations were likewise investigated. Both air drying and baked vitreous enamels applied to iron surfaces were given vigorous tests.

The tests revealed that the binder in many of the air-drying applications would dissolve in warm water, while others would dry sufficiently porous to permit corrosion to develop.

It was also found that sprayed metal

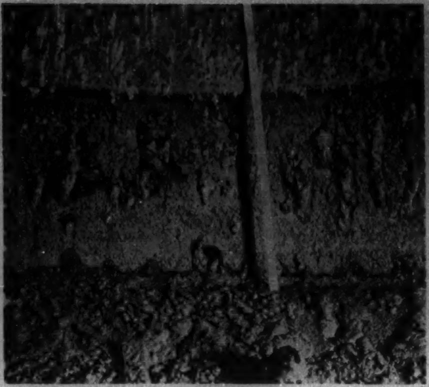

Figure 2. Tubercles on mercury-arc-rectifier water jacket

Figure 3. Electrolytic corrosion on mercury-arc-rectifier water jacket

would not make a sufficiently homogeneous surface to prevent water from reaching the iron. Similarly it was discovered that metals near the alkali end of the electromotive-force series would not long withstand the solvent action of the water. Therefore the effective life of metals of this nature would depend on the thickness of the coating.

Enameled surfaces in iron were found not sufficiently homogeneous to retard electrolytic corrosion. The application of vitreous enamels in preventing corrosion of rectifier surfaces was found very detrimental because any microscopic hole or crack in the enamel surface would take the total electrolytic current for the section and thus in a comparatively short time sufficient disintegration would occur to cause a vacuum leak.

Following the negative results of this initial investigation, it was decided to study methods of chemically treating the circulating water. For this test commercial corrosion-preventive liquids, oils, and many miscellaneous chemicals were studied. These were studied at constant and varying temperatures for their general and electrolytic corrosion-retarding qualities.

The study revealed several more or less promising treatments of the water for retarding general corrosion under the operating conditions of power rectifiers, but only one, a soluble chromate, $Na_2CrO_4 10H_2O$, effectively controlled both general corrosion and the intensified action due to electrolysis.

Sodium dichromate $Na_2Cr_2O_7 2H_2O$, is usually used to supply the chromate for a corrosion-inhibiting solution, because this salt is readily obtainable and is of low cost. Many natural waters are sufficiently alkaline to convert this to the chromate. Where this is not the case it is advisable to add the requisite alkali. This does not materially affect the anticorrosive action of the chromate, but may prevent a rapid loss of the chromate from certain unwanted side reactions due to impurities in the water.

As an example of the effectiveness of a sodium chromate-treated coolant, the photograph figure 4 is submitted, showing three iron electrodes, all immersed in their respective containers for 12 days. The electrodes were immersed in separate containers, *A*—the positive electrode of a cell containing Schenectady tap water, *B*—the positive electrode of a cell containing a one-half per cent solution of sodium chromate using Schenectady tap water. A five-volt potential was impressed between the electrodes of the two cells. Electrode *C* was placed in a container of Schenectady tap water, with no potential impressed. Electrode *C* is an example of the so-called general corrosion, a fairly uniform covering of reddish-brown iron oxide. No tubercles or concentrated corrosion is noted on this specimen. Electrode *A* shows the effect of electrolytic disintegration, much of the iron having been removed by the effect of the few milliamperes of current. As a contrast, electrode *B*, which was immersed in a sodium chromate solution shows on microscopic examination no evidence of either the so-called general or concentrated form of electrolytic corrosion. It is interesting to note that by virtue of the relatively high electrical conductivity of the sodium chromate solution, approximately ten times as much current was passed between the electrodes of this cell in comparison with electrodes of the cell containing tap water and electrode *A*. Subsequent tests where the cell current was increased several hundred per cent, indicated that even with this unusual current, the one-half per cent solution of sodium chromate was capable of inhibiting electrolytic corrosion.

This passivating action of the chromate is somewhat complex. Recent research[3] indicates that it is not a simple oxidizing action. Other powerful oxidants such as the permanganates and

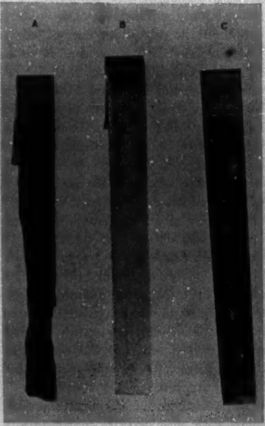

Figure 4. Three iron samples after corrosion test

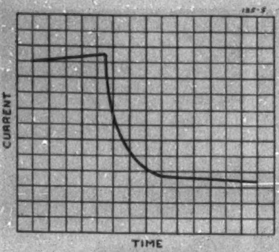

Figure 5. Current characteristic during growth of protective chromium film

hydrogen peroxide produce no such effect. The effectiveness of the protective oxide film produced, appears to be due not only to the simple production of a film of iron oxide but also to the inclusion of chromic oxide in the precipitate or rust formed in the simple corrosion reaction. This so modifies it that a dense and adherent protective film results rather than a loose nonprotective rust or tubercle. Of these factors the inclusion of Cr_2O_3, is probably the most important as the other action is also common to other oxidizing agents which have less or no protective effect.

The growth of the protecting chromate film is an interesting phenomenon, as shown in figure 5. With the deposition current as abscissa and time as ordinate we see what normally occurs in a few seconds or a few minutes, depending upon the chromate concentration and the existing difference in potential. The formation of the film takes place quickly, and then the deposition current which generally is of the nature of a few milliamperes, gradually recedes as the thickness of the film increases. Ultimately, the current reaches a minimum value. Laboratory cell tests made to determine the proper concentration of sodium chromate indicated, as would be expected, electrolytic corrosion at the positive terminal when untreated water is used. By the addition of a small amount of chromate it was noted that the effects of electrolytic corrosion became more pronounced. With each subsequent small increase up to a certain amount, the effects of electrolytic corrosion increased proportionally. When the critical amount was exceeded, it was noted that the evidence of electrolytic corrosion abruptly stopped.

The resistance of chemical solutions varies with their nature, concentration, and temperature, the higher-temperature solutions being the better electrical conductors. The chromate solution of the concentration used as the rectifier coolant is many times the better electrical conductor than is the average tap water. This fact is shown in the curves figure 6, where the electrical conductivity of Schenectady tap water and sodium chromate solution are shown at increasing temperatures. These relative curves show the trend of their respective conductivities as measured with one-sixteenth-inch diameter wire electrodes at a distance of one inch, and with current values approximating those found passing between different parts of the rectifier cooling system. The important consideration of these curves is that ample lengths of insulating coolant conductors must be provided between points of different electrical potential; so that the amount of leakage current will be negligible.

The application of chromate as a corrosion inhibitor is by no means new. Solutions containing chromate have been used for many years in the retarding of the general corrosion of iron.[4] The application of a sodium chromate coolant to specifically retard pitting corrosion in the steel-tank power rectifier, apparently is a new field of service.

The Applications of Sodium Chromate

The laboratory tests revealed that a one-half per cent solution of sodium dichromate was sufficient for the average water used as a rectifier coolant. This strength of solution has been found to be sufficient to inhibit corrosion when the solution is made up of any waters of potable purity. Where waters are available which are of exceptional purity, then it is possible to reduce the percentage of solution. A safe solution percentage can be determined definitely by the electrochemical means, explained below. Naturally the safest solution is made using distilled water, where the absence of foreign chemicals which would tend to react with the sodium dichromate and thus limit its life as a corrosion inhibitor is assured. Solutions made up of potable waters containing an excessive amount of chloride will require the full amount of sodium dichromate in order to obtain the full corrosion protection of the dichromate solution.

Before installing anticorrosive treatment in rectifier cooling systems, it is essential that all metal surfaces be perfectly clean. The coolant is made by adding a sufficient amount of the orange-colored sodium dichromate crystals of technical purity, to the water of the cooling system. A one-half per cent solution requires 4.2 pounds of the crystals to every 100 gallons of cooling water. The crystals are readily dissolved in cold or warm water and as soon as added to the system the coolant should be circulated.

The following method of checking the effectiveness of any given treated water has been found convenient and practical. A sample of the solution is placed in a glass bottle provided with two iron-wire electrodes spaced about one inch apart. Impress approximately five volts d-c potential across the electrodes. Should the solution be weak, a grayish-colored formation or precipitate will become visible within 5 to 30 minutes about the positive electrode, indicating anodic attack which may also be seen on close inspection of the electrode. The solution should then be strengthened and the test again repeated. Should the solution be of sufficient strength to retard corrosion, no precipitate will form around the electrodes. In order to eliminate any possible external influence, it is desirable that all such tests be made at a specific solution temperature maintaining the same size of bottle and dimensions for the electrodes.

Field Experience With Sodium Dichromate

Sodium dichromate has been used as a corrosion inhibitor in the steel-tank power rectifier since 1930. Since this time, all rectifiers in which the inhibitor solution was properly maintained have been free from both the general and concentrated pitting corrosion. Prior to the application of sodium dichromate, the temperature of practically all steel tank rectifiers, was controlled by tap water cooling. At the present time only 12 per cent of the rectifiers have tap-water temperature control, the remaining 88 per cent are provided with recirculating cooling sys-

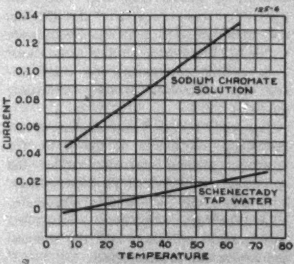

Figure 6. Electrical conductivity versus temperature

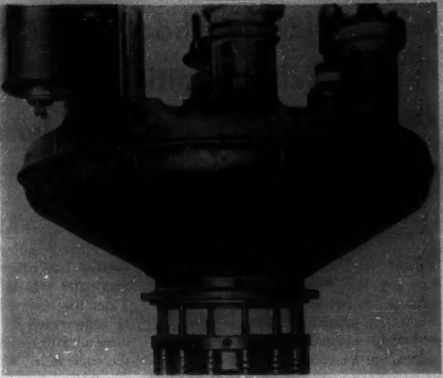

Figure 7. General Electric mercury-arc rectifier vacuum chamber after eleven months' operation with sodium dichromate coolant in place of tap water showing corrosion arrested

tems and treated water. Of the rectifiers originally operating with tap water cooling, approximately 25 per cent have experienced corrosion trouble terminating in vacuum leaks.

The life of a sodium dichromate solution depends upon the amount of make-up water added to the closed circulating system, and also on the chemical nature of the raw water. Our experience indicates that some solutions using mountain waters which are essentially pure, have a life in excess of three years. Well waters which are potable but have a higher impurity content, when made into an inhibiting solution have a life ranging upward from nine months. As already indicated, it has been found that the addition of small amounts of caustic soda ($NaOH$) to the chromate solution would increase its effective life. The function of the soda is to convert the inhibitor to a neutral chromate. A proportion of 1.5 ($NaOH$) to 5 ($Na_2Cr_2O_7 2H_2O$) ordinary crystalline dichromate, is sufficient in most cases. Slightly more ($NaOH$) than this proportion will do no harm. It has been found desirable to make periodic electrochemical examinations of the efficiency of an inhibiting solution; this can be done monthly or semiannually, depending upon the chemical nature of the water used, and the amount of water added for make-up.

Figure 7 shows the rectifier tank indicated in figure 1, but following the application of sodium dichromate. This rectifier had previously operated on a closed cooling system using untreated water, during which time the carbuncles, some shown in figure 1 had produced the pitting indicated. Following the first 11-month application, no new indications of pitting were evident and the vacuum chamber was in a clean condition as indicated in figure 7. Since this photograph was taken, this rectifier has been operating continually for the past six years without corrosion troubles.

Various Types of Cooling Systems

Sodium dichromate coolant is equally as well adapted to either water-to-water or water-to-air type of temperature regulators. The application of either type depends naturally on the particular installation. Locations such as the railway subways, where a comparatively high ambient temperature prevails at all times, the water-to-water temperature regulator is the most satisfactory. In such cases where the prevailing ambient temperature is slightly below the operating temperature of the rectifier, water-to-air temperature regulators can be applied.

Water has been found to be the most practical coolant where the heat to be removed is relatively high. In apparatus where the watts per square inch are relatively low, forced air, or circulating oil may be utilized. For certain applications, such as the cooling of rectifier mercury-condensation pumps, tap water cooling is the most practical. Here the amount of heat to be removed is small, the rate of water flow is low and the apparatus to be cooled is relatively small. The apparatus being small, makes it possible to confine the water cooling system in a copper jacket or copper cooling coils.

Low Ambient or Freezing Protection

Water cooling systems utilizing the recirculating principle can be protected from freezing by maintaining a higher temperature by means of jacket water heaters or by the use of a nonfreezing solution. Both systems have been found practical. Where tap water cooling is used, it may be necessary to lag the water piping sufficiently to prevent freezing, and insure that a constant water flow is maintained.

Maintenance of Cooling Systems

All cooling systems require a certain degree of maintenance, depending upon the nature or chemical content of the water used.

Closed cooling systems utilizing sodium dichromate as corrosion inhibitor have been found to require the least attention. Many systems have operated for several years without the necessity of cleaning.

Tap water-cooled apparatus must be descaled frequently to prevent water stoppage. Here again the frequency of cleaning will depend upon the amount of mineral water in solution and the amount of matter in suspension, both of which will eventually clog the water system. Copper water piping is no exception. It also readily scales, but naturally will not corrode as iron pipe does. Water containing excessive amounts of chlorine has increased corrosion effect on iron piping. Water containing much algii, or manganese dioxide, makes frequent cleaning of the water system necessary.

Electrical Insulation of Water Systems

In order to insulate a water-cooled apparatus or a part of the apparatus from parts of higher or lower potential, the coolant is conducted through insulating tubing such as rubber hose or rigid tubing. The two ends of an insulating tubing containing a coolant in general form the terminals of an electrolytic cell. It is natural that electrolytic disintegration will be expected at the positive terminal with electrolytic deposition on the negative end. In order to retard the accelerating form of corrosion in the cooling system, so-called "electrolytic leads" have been applied which consist of a long metallic rod of positive potential which gradually disintegrates whenever a difference of potential exists in between the ends of the insulating tubing. The disintegration of the metallic rod prevents the metal ends of the insulating tubing from disintegrating and will last several months or years, depending upon the prevailing

A New Method for Introducing Relaxed Initial Conditions in Transient Problems

WALTER C. JOHNSON
ASSOCIATE AIEE

IN the calculation of transients in linear electrical and mechanical systems by the classical methods of differential equations, the constants of integration which arise in the solution are ordinarily evaluated from the initial values of the dependent variable and its derivatives.[1,2] The process of finding the initial derivatives is sometimes difficult for even rather simple systems, and the difficulties are particularly pronounced when the system of equations has undergone a change of variable to remove variable coefficients, as for example in Park's equations for the synchronous machine.[3] The purpose of this paper is to present a new method by which the initial derivatives can be found for an initially relaxed system (all currents in inductances and all charges on condensers initially zero) by a manipulation of the final differential equation itself. The solution for a nonrelaxed system can be found from the relaxed solution by superposition or by means of a systematic change in the original differential equations themselves, as is commonly done in operational calculus.[1,4,5]

The Differential and Integral Operators

The procedure in determining initial derivatives directly from the differential equation is based on the properties of the differential operator p (sometimes designated instead by the symbol D) and the integral operator $1/p$. It is shown in elementary treatments of linear constant-coefficient differential equations that if the derivative dy/dt be written py, where p indicates the operation d/dt, then p has many of the manipulative properties of an algebraic coefficient. Thus the second derivative d^2y/dt^2 can be represented by $p(py)$ or p^2y, and the integral with respect to time $\int y\,dt$, being the operation which cancels the first derivative, can be written symbolically $(1/p)y$. Similarly the iterated integral $\int\int..\int_n y dt$ is written $(1/p^n)y$.

In an initially relaxed system, all currents and voltages are zero for negative time. It is therefore possible in such a system to interpret the indefinite integral operator $1/p$ to mean the definite integral from 0– to t. The assignment of these limits does not interfere with the previous definition of $1/p$ as the indefinite integral, for the variable upper limit t provides this indefinite integral, and the lower limit merely supplies the proper constant of integration.

Examine next the integral $\int_{0-}^{t} y\,dt = (1/p)y$ as the upper limit of integration t approaches zero. It is evident from elementary integral calculus that under this condition the value of the integral approaches zero also, provided that y is not infinite at $t=0$. Thus we can write the useful relation

$$\lim_{t\to 0}\frac{1}{p}y=0 \tag{1}$$

which holds whenever the system is without energy at $t=0$, provided that y is finite at this time.

It will be observed that it is the quantity $(1/p)y$ and not $(1/p)$ itself which is zero at zero time. This is because $1/p$ is an operator and not merely a multiplier. The distinction will save much confusion, since if we wrote $1/p=0$ we should feel obliged to write $p=\infty$ at $t=0$. This, of course, is not correct, and will be avoided by observing that $(p)y$ is not the reciprocal of $(1/p)y$, and hence is not necessarily infinite when $(1/p)y$ is equal to zero.

The Problem

In the usual circuit problem a differential equation is set up for each mesh of the network, using Kirchhoff's laws. By expressing all of the derivatives and integrals in operator form and by manipulating the operator p as an algebraic coefficient, algebraic methods of solving simultaneous equations can be used to eliminate all of the dependent variables (e.g., currents) except the desired one. In doing this care must be exercised not to take any indicated derivatives but instead to retain all p's in operator form. By convention all operators are written to the left of the currents and voltages on which they operate. The resulting differential equation in terms of the desired variable is of the general form:

$$\phi(p)i=F_1(p)e_1(t)+F_2(p)e_2(t)+\,.\,. \tag{2}$$

in which

$e_1(t)$ is the voltage (in general a function of time) impressed in mesh number 1
$e_2(t)$ is the voltage impressed in mesh number 2, etc.
$\phi(p)$, $F_1(p)$, $F_2(p)$, etc., are polynomials in p

The polynomial $\phi(p)$ is generally as high or higher in degree of p than $F_1(p)$, $F_2(p)$, etc. If $\phi(p)$ is lower in degree of p than some $F(p)$, as is the case when solving for the current in a circuit in which a complete path through condensers exists between input terminals, the response i may contain an infinite impulse at $t=0$, and equation 1 will no longer hold. This difficulty can be eliminated by rewriting the differential equation in terms of charge q, where $pq=i$, and later taking the derivative of the solution for q to find the form of i.[1]

It is known from differential-equation theory that for any given system of differential equations there is one and only one set of solutions which is zero for negative time, and hence for any dependent variable in the system there is one and only one set of initial derivatives

which satisfy the condition of initial relaxation. We now desire to obtain directly from the differential equation 2 the values of these derivatives of the dependent variable i as t approaches zero from the positive side. In general, if $\phi(p)$ is of the nth degree, it is sufficient to know the initial values of the dependent variable and its first $n-1$ derivatives.

The Procedure

Since we know from the discussion in a preceding section that for an initially relaxed nonimpulsive system all integrals of current and voltage must be zero at $t=0$, it is advantageous to first put the differential equation 2 into integral form by dividing through by p to the highest power found in $\phi(p)$.* It will then be found that by making t and the various integrals $1/p$, $1/p^2$, etc., equal to zero everywhere in the integral equation, the initial value of current, $i(0)$, can be found immediately. Here t is considered to approach zero from the positive side.

To find the initial value of the first derivative of current, $i'(0)$, take the first derivative of the integral equation in a symbolic manner by multiplying through by p, take all indicated derivatives (denoting them by primes where necessary), and again set t and the various integrals $1/p$, $1/p^2$, etc., equal to zero everywhere. Solve for i', which will be di/dt at $t=0$ or $i'(0)$, where t is considered to approach zero from the positive side.

To obtain the initial value of the second derivative, multiply the integral equation through by p^2 and repeat the process. This procedure can be continued indefinitely until the required number of initial derivatives has been found. The process must be a successive one since each derivative will be expressed in terms of lower derivatives.

Since the method requires only the formation of the integral equation and the application of the fact that in an initially relaxed nonimpulsive system the various integrals of current and voltage are zero at $t=0$, it is simpler to apply the process to each problem separately without attempting to derive formulas.

Examples

(1) An A-C Circuit

The differential equations for the circuit shown in figure 1 can be written as:

$$(R+1/pC)i_1-(1/pC)i_2=E\sin\omega t$$
$$(-1/pC)i_1+(1/pC+pL)i_2=0 \qquad (3)$$

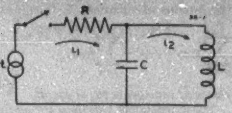

Figure 1. Circuit of example number 1

The elimination of i_2 by algebraic methods yields:

$$\left(RLp^2+\frac{L}{C}p+\frac{R}{C}\right)i_1=\left(Lp^2+\frac{1}{C}\right)E\sin\omega t \qquad (4)$$

The steady-state current can be found by the usual complex impedance method:

$$i_{ss}=\frac{E}{|Z|}\sin(\omega t-\phi)$$

where

$$Z=R+j\frac{\omega L}{1-\omega^2LC}$$

and

$$\phi=\tan^{-1}\frac{\omega L}{R(1-\omega^2LC)}$$

If the roots of the characteristic equation $(m^2RL+mL/C+R/C)=0$ are $m=-a_1,\ -a_2$, the total current is given by the expression:

$$i_1=\frac{E}{|Z|}\sin(\omega t-\phi)+C_1\epsilon^{-a_1t}+C_2\epsilon^{-a_2t} \qquad (5)$$

where C_1 and C_2 are the constants of integration to be determined from the initial conditions.

To find the relaxed initial derivatives, return to differential equation 4 and rewrite it as an integral equation by dividing through by p to the highest power found on the left side, p^2. This yields:

$$\left(RL+\frac{L}{C}\frac{1}{p}+\frac{R}{C}\frac{1}{p^2}\right)i=\left(L+\frac{1}{C}\frac{1}{p^2}\right)E\sin\omega t \qquad (6)$$

For the initial value of i, set t and the integrals $1/p$ and $1/p^2$ equal to zero in the integral equation 6. Then we have

$$(RL+0+0)i=(L+0)E\sin(0)$$

or

$$i(0)=0$$

For the initial value of di/dt, take the first derivative of the integral equation 6 by multiplying through by p. Then, taking the indicated derivatives and setting t and the various integrals equal to zero, we obtain:

$$RLi'(0)+\frac{L}{C}i(0)+0=LE\omega\cos(0)+0$$

or, since $i(0)=0$,

$$i'(0)=\frac{\omega E}{R}$$

Substituting these two conditions for time $t=0$ into the solution 5 and its first derivative, two equations in terms of the Cs are obtained:

$$C_1+C_2=\frac{E}{|Z|}\sin\phi$$

$$a_1C_1+a_2C_2=\omega E\left[\frac{\cos\phi}{|Z|}-\frac{1}{R}\right]$$

When the equations are solved simultaneously for the Cs, and these substituted into equation 5, the result is the complete solution for an initially relaxed system:

$$i_1=\frac{E}{|Z|}\left[\sin(\omega t-\phi)+\frac{(R\omega\cos\phi-Ra_2\sin\phi-\omega|Z|)\epsilon^{-a_1t}+(Ra_1\sin\phi-R\omega\cos\phi+\omega|Z|)\epsilon^{-a_2t}}{R(a_1-a_2)}\right]$$

(2) Solution of an Oscillatory Circuit

The circuit shown in figure 2 is one in which the initial value of the first derivative of input current is very difficult to find by ordinary means, and where the operational solution becomes rather laborious because of complex quantities which must be rationalized.

The differential equation for the input current can be shown to be:

$$\left[p^2L(R_1+R_2)+p\left(R_1R_2+\frac{L}{C}\right)+\frac{R_1}{C}\right]i=\left(p^2L+pR_2+\frac{1}{C}\right)E \qquad (7)$$

If the circuit is oscillatory a convenient form of the solution is:

$$i=\frac{E}{R_1}+\epsilon^{-at}(A\sin\omega t+B\cos\omega t) \qquad (8)$$

where

$$a=\frac{R_1R_2+L/C}{2L(R_1+R_2)}$$

$$\omega=\sqrt{\frac{R_1}{LC(R_1+R_2)}-\frac{(R_1R_2+L/C)^2}{4L^2(R_1+R_2)^2}}$$

To find the successive initial derivatives, first obtain the integral equation by dividing differential equation 7 through by p^2. Set the various integrals equal to zero and obtain

$$[L(R_1+R_2)+0+0]i=(L+0+0)E$$

or

$$i(0)=\frac{E}{R_1+R_2}$$

To find the initial value of the first derivative, multiply the integral equation through by p, take the indicated derivatives, and set the various integrals

---

*For a proof of the method, see the appendix.

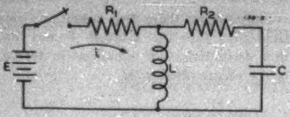

Figure 2. Circuit of example number 2

equal to zero. This yields

$$L(R_1+R_2)i'(0)+(R_1R_2+L/C)i(0)+0=\\ 0+R_2E+0$$

and since the value of $i(0)$ has just been found, we can solve for the desired $i'(0)$, obtaining:

$$i'(0)=\frac{E(R_2^2-L/C)}{L(R_1+R_2)^2}$$

If these values of i and i' are substituted into the solution 8 and its first derivative at $t=0$, we find that

$$A=\frac{E}{2\omega L(R_1+R_2)^2}\left[R_2^2-\frac{L}{CR_1}(2R_1+R_2)\right]$$

$$B=\frac{-ER_2}{R_1(R_1+R_2)}$$

The complete solution for relaxed initial conditions can now be written from equation 8 by substitution of these values for A and B. The solution has been obtained in a simple and direct manner, and has avoided a rather laborious manipulation of complex numbers.

Appendix—Proof of Method of Determining Initial Derivatives

Consider the system of differential equations:

$$\sum_{j=1}^{n}(a_{ij}p+b_{ij})x_j=f_i(t),\quad i=1,2..n \tag{9}$$

Let this system be written in terms of continuous variables, for example if current is discontinuous, write the equations in terms of charge. Where second derivatives occur, introduce a new variable z such that:

$$px_j-z_j=0 \tag{10}$$

The second derivative p^2x_j can then be written pz_j, and equation 10 will form part of system 9.

Since the system is linear, the various terms $f(t)$ can be introduced one at a time, and the total solution found by the superposition of the separate solutions. It is therefore sufficient to prove that the method is correct with only one $f(t)$ present. Hence let:

$$\begin{aligned} f_i(t)&=f(t) \quad \text{for } i=1\\ &=0 \quad \text{for } i\neq 1 \end{aligned} \tag{11}$$

First find the initial values of the derivatives of x_k by solving the system of equations 9 for time $t=0$. To do this, transpose the b-terms of equations 9, thus obtaining:

$$\sum_{j=1}^{n}a_{1j}x_j'=f_1(t)-\sum_{j=1}^{n}b_{1j}x_j \tag{12}$$

where x_j' represents px_j or dx_j/dt.

The independent variables are continuous, so $x_j(0+)=0$. Let $t=0$ in equations 12 and solve the system for $x_k'(0+)$. Then:

$$x_k'(0+)=\frac{M_{1k}}{D}f(0+) \tag{13}$$

where D is the determinant of the a's, and M_{1k} is the minor obtained by striking out the first row and kth column of this determinant and attaching the sign $(-1)^{k+1}$.

Differentiate equations 12 once, set $t=0$, substitute equation 13, and solve for $x_k''(0+)$, which is d^2x_k/dt^2 at $t=0+$.

$$x_k''(0+)=\frac{M_{1k}}{D}f'(0+)-\\ \frac{f(0+)}{D^2}\sum_{i=1}^{n}\sum_{j=1}^{n}b_{ij}M_{ik}M_{1j} \tag{14}$$

This process can be continued indefinitely to find the initial values of higher derivatives.

It will now be shown that the same results are obtained by means of the new method. Return to the original system of equations 9 and eliminate all of the dependent variables except x_k. This yields:

$$(A_0p^n+A_1p^{n-1}+\ldots+A_n)x_k=\\ (B_1p^{n-1}+B_2p^{n-2}+\ldots+B_n)f(t) \tag{15}$$

where

$$A_0=D$$

$$A_1=\sum_{i=1}^{n}\sum_{j=1}^{n}b_{ij}M_{ij} \tag{16}$$

$$\vdots$$

$$B_1=M_{1k}$$

$$B_2=\sum_{i=2}^{n}\sum_{\substack{j=1\\ j\neq k}}^{n}b_{ij}M_{1i,jk}$$

$$\vdots$$

in which $M_{1i,jk}$ represents the second minor of the determinant D obtained by striking out the first and ith rows and the jth and kth columns, and attaching the sign $(-1)^{1+i+j+k}$ for $j>k$ and $(-1)^{i+j+k}$ for $j<k$.

Applying the new method of determining initial values of derivatives to equation 15, we find that:

$$x_k(0+)=0 \tag{17}$$

$$x_k'(0+)=\frac{M_{1k}}{D}f(0+) \tag{18}$$

$$x_k''(0+)=\frac{M_{1k}}{D}f'(0+)+\\ \frac{f(0+)}{D^2}\left[\sum_{i=2}^{n}\sum_{\substack{j=1\\ j\neq k}}^{n}b_{ij}DM_{1i,jk}-\right.\\ \left.\sum_{i=1}^{n}\sum_{j=1}^{n}b_{ij}M_{ij}M_{1k}\right] \tag{19}$$

Equation 17 is correct by virtue of the continuity of the x's, equation 18 checks with equation 13 as obtained by the other method, and comparison of equation 14 with equation 19 shows that the following condition must be satisfied:

$$\sum_{i=1}^{n}\sum_{j=1}^{n}b_{ij}M_{ik}M_{1j}=\\ \sum_{i=1}^{n}\sum_{j=1}^{n}b_{ij}M_{ij}M_{1k}-\\ \sum_{i=2}^{n}\sum_{\substack{j=1\\ j\neq k}}^{n}b_{ij}DM_{1i,jk} \tag{20}$$

The coefficients of the b's must be separately equal. Because of the conditions on the last summation, three cases must be distinguished:

Case I. i = 1, j unrestricted

The coefficients of b_{1j} as obtained from equation 20 are:

$$M_{1k}M_{1j}=M_{1j}M_{1k}$$

which is an identity.

Case II. i unrestricted, j = k

The coefficients of b_{ik} in equation 20 are:

$$M_{ik}M_{1k}=M_{ik}M_{1k}$$

Case III. i ≠ 1, j ≠ k

The coefficients of b_{ij} yield the following relation which must be satisfied:

$$M_{ik}M_{1k}-M_{ik}M_{1j}=D\cdot M_{1i,jk} \tag{21}$$

The left side of equation 21 can be written as an nth order determinant, which, when multiplied by the determinant D rearranged with the former kth and jth columns as the first and second columns, and with the former ith row shifted to the second row, yields the following result:

$$\begin{vmatrix} a_{1k} & a_{1j} & a_{11} & \ldots & a_{1n}\\ a_{ik} & a_{ij} & a_{i1} & \ldots & a_{in}\\ a_{2k} & 2_{2j} & a_{21} & \ldots & a_{2n}\\ \vdots & \vdots & \vdots & & \vdots\\ \cdot & \cdot & \cdot & & \cdot\\ a_{nk} & a_{nj} & a_{n1} & \ldots & a_{nn} \end{vmatrix} \cdot \begin{vmatrix} M_{1k} & M_{ik} & 0 & 0 & \ldots 0\\ M_{1j} & M_{ij} & 0 & 0 & \ldots 0\\ M_{11} & M_{i1} & 1 & 0 & \ldots 0\\ M_{12} & M_{i2} & 0 & 1 & \ldots 0\\ \vdots & \vdots & \vdots & \vdots & \vdots\\ M_{1n} & M_{in} & 0 & 0 & \ldots 1 \end{vmatrix} =\\ \begin{vmatrix} D & 0 & a_{11} & \ldots\ldots & a_{1n}\\ 0 & D & a_{i1} & \ldots\ldots & a_{in}\\ 0 & 0 & a_{21} & \ldots\ldots & a_{2n}\\ \vdots & \vdots & \vdots & & \vdots\\ \vdots & \vdots & \vdots & & \vdots\\ 0 & 0 & a_{n1} & \ldots\ldots & a_{nn} \end{vmatrix}$$

The left side is equal to $(-1)^{i+j+k+1}D[M_{ij}M_{1k}-M_{ik}M_{1j}]$ for $j>k$ and to $(-1)^{i+j+k}D[M_{ij}M_{1k}-M_{ik}M_{1j}]$ for $j<k$. The right side, when expanded, is found to be equal to $(-1)^{i+j+k+1}D^2\cdot M_{1i,jk}$ for $j>k$ and to $(-1)^{i+j+k}D^2\cdot M_{1i,jk}$ for $j<k$, so therefore:

$$M_{ij}M_{1k}-M_{ik}M_{1j}=D\cdot M_{1i,jk}$$

which was to be proved.

If the differential equation 15 had been written in terms of a variable with a simple discontinuity at $t=0$, say in terms of the first derivative of x_k, each term on the right side of equation 15 would have been raised once in power of p. The method will yield the proper initial values in this case also, for the initial value of the new variable will be equal to the first derivative of the old, and so on. The method is therefore applicable to variables with a simple discontinuity at $t=0$, as well as to variables which are continuous everywhere.

The Varioplex—a New Development in Telegraphy

E. R. SHUTE
MEMBER AIEE

Synopsis: The varioplex method of telegraphic operation provides each pair of stations connected together by it an ever-ready two-way channel for the exchange of traffic, which occupies a band width of zero when idle and of a variable width when busy, depending upon extent of simultaneous usage by other connected stations. It possesses certain advantages over, or in supplement to, other forms of manual and machine switching or repeatering. Adapted to the use of private subscribers through telemeter service, it is finding extensive application in the telegraph plant.

A GOOD deal of current effort in the telegraph engineering field is being directed toward the solution of problems of trunking and switching. Basically, these problems arise from the circumstance that important trunking centers, like Boston, Atlanta, or Los Angeles, have tributary to them most of the less important telegraph offices in their respective surrounding areas. That this is so with respect to the many branch telegraph offices and tie-line connections which dot the larger American cities requires no explanation; the growth of commerce along the railroads has made it no less true of cities and towns many miles from trunking centers. The existence of fanned-out local telegraph circuits around Boston as a hub, to take that city as an example, is inherent in the commercial relationship of most New England towns to its dominating city. It can be appreciated, then, why the Boston office, in years past, has acted not only as the terminal for a considerable day-to-day traffic between Taunton and Boston but also as the relay point for the less frequent messages between Taunton and New York. This situation exists the country over. Of recent years, improvements in the transmission qualities of these tributary circuits have made it possible to terminate them, almost universally, in printing telegraph equipment.

Between the larger cities for years there have existed the more heavily loaded trunk wires, over which has flowed traffic manually fed to them by the tributary networks. Through the use of synchronously-operating multiplex distributors, the capacity of these intercity trunk facilities has been made conveniently divisible into units called traffic channels, of an output adapted to the capabilities of operators. These channels operate at speeds of from 60 to 75 words per minute. The gradual standardization of printer equipment, the stabilization of unit capacities, and the adaptability of printer circuits to end-on repeatering have together extended an open invitation to engineers to increase the number of trunk channels regularly connected, or temporarily connected on demand, to other trunk channels and to fanned-out tributary trunks and tie lines, thus markedly increasing the number of pairs of cities, pairs of towns, of branch offices, and of customers, directly tied together by traffic channels.

In creating such through channels between distant terminals, recourse has been had to end-on switching of a variety of types of circuit constituting the intervening geographical circuit sections. Some have been of start-stop, others of the multiplex time-division, or sector, type; some have been routed over duplexed ground-return physical conductors, others over metallic loops, or over composite or superimposed d-c pairs, or over a-c carriers; and either with or without electromechanical storage en route.

The type of switching adopted for increasing the length and number of these standard-width traffic channels has been influenced in part by the holding time of the connections. Where day-by-day connection of intercity trunks has been desirable, fork-series connection of multiplex channels,[1] and extended start-stop channels,[2] have produced efficient results. Where telegraph-talk connections have had to be quickly set up and pulled down[3] in a manner similar to that employed in connecting long-distance telephone calls, the general pattern of toll switching[4] has been followed. Where the bulk of the traffic is single-shot, forms of dial machine switching[5] have proved advantageous. In the admixture of all types of traffic in a large office installation, the manual switching of reperforators[6] has been successful. All these methods have been, and still are, significant in telegraphy as it is being developed in the United States today.

The Varioplex Concept

Whatever the form of switching, switched telegraph channels, up until the present time, have had in common the characteristic of occupying a frequency band of constant width, whether busy or idle. Although not standardized, such bands have been of the order of 20 cycles per second in width, accommodating traffic at a rate, representatively, of 65 words a minute.

Against the foregoing background of progress, Philo Holcomb, Jr., the author of a companion paper[7] before this convention, originally projected the concept of, and devised the circuits for, a telegraphic "lane" for traffic, of variable, rather than of constant, width—a lane whose width occupied the full capacity of a geographical circuit section at times when that lane alone was being accommodated—a lane whose width adjusted itself automatically to occupy only its proportionate share of a component circuit section at times when that circuit section was simultaneously accommodating other lanes of traffic—and, most important of all, a lane for traffic whose

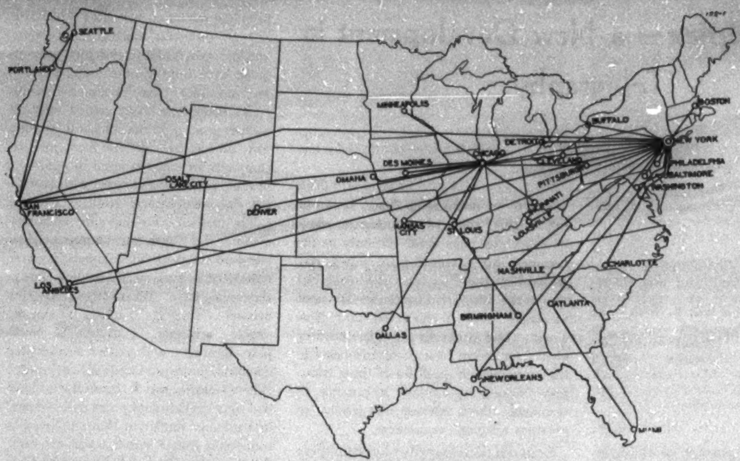

Figure 1. Map of varioplex systems in United States

width decreased to zero, automatically, whenever no traffic happened to be passing over the lane.

It was at once obvious that with such an expanding, contracting, variable-width lane, it would be practicable, ultimately, to set up a multiplicity of direct connections theretofore considered out of the question because of light loads. For the lane width now having been reduced to zero when idle, there remained no necessity to deny to two telegraph offices or to two tie-line customers or subscribers a direct lane for traffic merely because the load offered happened to be small in relation to the total capacity of a 20-cycle-per-second channel of multiplex over which it might be switched.

An important part of the concept was that the effect of switching thus secured was to be accomplished, not manually as by a plug-and-jack switchboard, nor automatically as by dialing a number, but by the expedient of providing that the two terminals should always remain interconnected through the system but completely "inert" until traffic was offered. The fundamental switched informational unit was to be, not the duration of a toll call, not the length of a series of messages or even of one telegram, but the amount of information transmitted by the operator without pause, be that the extreme length of a press dispatch or, at the other extreme, the length of one word, a numeral, or even a solitary letter.

Applications

The original concepts and circuits were developed by the Western Union engineering department and the systems given the name of varioplex. The map, figure 1, shows the extent of application of such systems, and the photograph, figure 2, depicts the installation of 4 out of the 16 systems terminating in the main telegraph office in New York City. The 39 systems operate over 92 channels of standard duplex multiplexing equipment and provide 736 unidirectional lanes, or 368 two-directional "subchannels" as they are referred to, of communication.

A typical varioplex system is that set up between Los Angeles and San Francisco, consisting of 27 subchannels. Twenty-two of the 27 subchannels provide direct two-way printer operation between 22 pairs of San Francisco and Los Angeles branch offices or subscribers' tie lines, the business between which hitherto would have had to be carried on 22 individual wires or manually relayed in San Francisco and again in Los Angeles. The remaining five subchannels provide Los Angeles Western Union with direct connection to offices in Seattle, Chicago, Sacramento, Oakland, and Reno, through flexible linkage at San Francisco. In the case of the Seattle connection, the Los Angeles-San Francisco varioplex subchannel is connected to a San Francisco-Seattle varioplex subchannel; a similar connection is made at San Francisco on a varioplex subchannel going through to Chicago. In the case of Sacramento and Oakland, physical wires carrying start-stop teleprinter signals between those cities and San Francisco are repeatered separately at San Francisco into the two varioplex subchannels to Los Angeles. In the case of Reno, a multiplex channel

Figure 2. Four of 16 systems of varioplex apparatus in New York main office

between Reno and San Francisco is coupled to the Los Angeles varioplex subchannel at San Francisco.

Capacity

Sixty-six words per minute has been adopted as the standard multiplex channel speed for varioplex systems. The total capacities of such systems are, therefore, 66, 132, 198, and 264 words per minute in each direction, depending upon whether the varioplex system is carried over one, two, three, or four channels of multiplex. The Los Angeles-San Francisco system referred to is of 264 words capacity.

Some idea of the flexibility of varioplex systems may be gained by consideration of the equipment of three multiplex channels on a physical wire (or two unidirectional channels of audio-frequency telegraph carrier) between New York and St. Louis. One of the channels is retained in use as a duplex printer trunk; the second carries a three-subchannel varioplex system; the third carries a six-subchannel varioplex. By way of comparison, the Chicago-Los Angeles varioplex of six subchannels occupies the combined capacity of all three multiplex channels.

The type of varioplex system chosen and the number, type, and traffic loading of the subchannels assigned to it, are matters tied up with the time, frequency, and duration of the occurrence of peaks of simultaneous demand for facilities. The maximum number of subchannels now assigned to a varioplex system in service is 36. It is thought that this figure by no means represents the upper limit of lightly loaded subchannels which ultimately will economically be so assigned. If all 36, or all 48, 99, or whatever the upper limit may prove to be—if all the connected load were to demand simultaneous use of the circuit, the speed per channel would be very low indeed, the total to be divided among all being only, say, 264 words per minute. In practice, however, the maximum simultaneous demand has been recorded at only nine subchannels on this 36 subchannel system; each channel was operating at 29 words per minute during the period of maximum demand. The usual condition of simultaneous demand has been found to lie between two and five channels on this 36 subchannel system. Since all subchannels enjoy full speed of 66 words per minute on this circuit until the fifth subchannel cuts in, it may be said that only occasionally is the speed ever reduced from that figure, and in such cases only down to 53 words per minute for brief intervals.

When, because too large a number of varioplex subchannels are in simultaneous use their respective speeds are unreasonably low, the obvious cure is to reassign the subchannels. Examination into the causes of abnormal simultaneous usage has often pointed the way to corrective action. Low subchannel speed is not a defect of the varioplexing process, for the situation on the superseded multiplex under the conditions of manual operation and with the same concentrated fall of traffic would be even worse. For a given fall of traffic the varioplex packs the informational content more compactly into the available transmission band width than does any other form of telegraphy. If a multiplex circuit between New York and Seattle has a capacity of 100 messages per hour and satisfactorily handles all the traffic on a manual-relay basis between the New York and Seattle areas, experience has pointed to the conclusion that all the offices in those areas could, if desired, be interconnected by varioplex over the long haul and there would be no excessive demand peak, and no unreasonably low channel speeds would be encountered. In fact, it would be found that more offices and more traffic could be added to the connected load without encountering trouble.

Occasional reduction of speed is noticeable to a receiving operator watching a printer working on a varioplex subchannel. From the viewpoint of the sending operator, however, there is no difference between varioplex and teleprinter transmission. The line from the sending printer on each operating table is connected to an individual distributor and automatic perforator combination at the varioplex terminal, shown in figure 3. This combination converts the seven unit start-stop signals from the sending printer keyboard to a perforated paper tape in the usual five-unit multiplex code. The sending line and distributor-perforator combination are continuously available to the operating table so that the sending operator may send at any time at the full teleprinter speed of 65 words per minute. Thus is met the requirement of a continuously available full-speed channel for the transmission of traffic from the operating position. Regardless of the speed variations that may exist in transmitting the characters over the trunk channels, the full capacity and efficiency of the sending operator may be utilized whenever traffic is on hand for transmission.

Advantages

Regardless of the extent to which the varioplex has already been installed, its full potentialities in increasing the efficiency of utilization of trunk circuits and equipment may not yet have been fully realized. A telegraph informational transmission band is essentially very narrow—of the order of 20 cycles per second or less, as pointed out before. To assign a physical wire to its transmission is an unconscionable waste from an engineer's standpoint. To assign to it a carrier with comparatively wide intercarrier spacing is only slightly more pardonable. Interlocking multiplexed channels are more efficient as to band width occupied, but even here the fixed width of each of the channels admits of no conformation either to the human limitations of the operators or to the vagaries of the fall of traffic. Surveys of trunk groups with a mixture of physical, derived, and carrier circuits employed in diverse services have shown an unused capacity as high as 70 per cent on facilities considered "full." Divided into units of capacity of 60 to 70 words per minute, there were, literally, no facilities to be spared in the groups under survey. Only by varioplexing all facilities in such circuit groups can 100 per cent utilization be approached. One great contribution of the varioplex to the telegraph art is that its flexibility makes available for traffic many of the heretofore idle cracks and corners of the telegraph wire-plant capacity.

A second important advantage of the varioplex is that no matter how heavily congested one or more of the circuit sections may be over which the lane for traffic is connected, transmission of the first character of every message initiated is started immediately and completed forthwith, from origin to destination, as soon as the keyboard is manipulated. There is no testing for idle channels, no busy signals are received, no time is wasted in handling dial-switching impulses, there is no additive delay due to such impulses traversing the chain of connection, no waiting for a particularly long message to clear out of the way. Since all varioplex connections are, in essence, perpetually connected two-way circuits, there is no waiting involved on the part of the sending office for a quick acknowledgment of receipt on the part of the receiving office.

A third major advantage which the varioplex contributes to the art is the compounding of possibilities of elimination of manual relaying of telegraphic information. While other modern meth-

Figure 3. Racks containing equipment for nine type C varioplex subchannels

ods of switching channels accomplish a similar purpose, their scope has been limited by the requirement that, to justify economical switching, the switched informational unit must contain a practical minimum number of words. Elimination of such an economic minimum through the varioplex principle throws open a wide field of development for switching, with all its demonstrated advantages over manual relaying. The number of operations and the amount of supervision are reduced—so are investment, operating maintenance, and inspection costs of belt conveyors, branch-office pneumatic tubes, printers, perforators, typewriters, and stationery. So too are routing and servicing costs cut down. Because varioplex repeaters require much less room than corresponding channels for manual relaying, there are additional savings in rental items.

A fourth advantage of the varioplex is, in a sense, a derivative of the other three in their application to the use of public telegraph facilities by private communication systems. By employing varioplex subchannels, users need no longer choose between the continuous utilization of a full standard-width communication channel on the one hand and a discontinuous service on the other. Varioplex connections between two private customers afford them teleprinter intercommunication at any time without the necessity of ordering a circuit to be made up and without any impulse to hurry or terminate a conversation through lapse of time alone. Opportunity is thus afforded for deliberation between questions and answers and for consulting files, assistants, and authorities. To utilize a varioplex subchannel for this type of service it is necessary only to present a sufficient volume of traffic to pay the costs of providing the subchannel equipment; the charge may then be based on volume rates for the traffic actually handled. A metering instrument incorporating a character counter has been developed for such an application, and the varioplex facility is now widely used by subscribers under the name of telemeter service.

Conclusion

The increase in the efficiency of utilization of trunk-circuit capacity effected by the use of varioplex equipment is an obvious and worth-while contribution to telegraph progress. The dissociation of subchannels for point-to-point communication from the use of trunk-circuit capacity except when traffic is actually being transmitted is reflected in a greater return on investment in lines and terminal equipment. In laying out point-to-point channels for the handling of commercial telegraph traffic operating engineers need no longer be bound by former limitations as to traffic volumes. To establish a direct channel of communication, a volume of traffic sufficient to justify the use of a fixed amount of trunk-circuit capacity represented by at least one full trunk channel has in the past been necessary. Assuming that the total traffic between the areas concerned justifies the use of varioplex equipment as many individual subchannels as needed can be set up, it being necessary for the loads on these individual subchannels to be sufficient to justify only the subchannel operating equipment and the equipment for connecting it into the varioplex system. This possibility is further multiplied through the interconnection of subchannels from two or more systems to effect direct connections between areas not directly served by individual varioplex systems.

Experience is now beginning to reveal the optimum economic usage of methods of machine-switching, reperforation, and varioplex. Many interesting combinations are possible. Long-haul, intercity varioplex channels may be dialed by various branch offices in the city of origin, and fanned out by manually-switched reperforators in the cities of destination. Thus is indicated a material increase in the number of direct connections between telegraph offices and a resulting better telegraph service to the American public.

Power Supply for Resistance-Welding Machines—III

Factory Wiring for Resistance Welders

AIEE COMMITTEE ON ELECTRIC WELDING
Subcommittee on Power Supply for Welding Operations*

Purpose of Report

AN adequate power supply is one of the requisites of present-day, high-production resistance welding. A major part of the power supply system of any industrial plant lies within the plant itself and consists of the plant wiring and transformer substations. It is the purpose of this report to show how to properly lay out such a plant distribution system for serving welders. Much of the fundamental data included in the tables and charts is not new but is included in order that the layout engineer will have complete information available in one compact report and will not have to refer to various articles and handbooks, copies of which may not be readily available.

General Considerations

The first report of this series, "Guide to Good Electrical Performance of Resistance Welding Machines," pointed out the need for keeping welder kilovolt-ampere inputs as low as possible for given welding current outputs, and the next step consists of providing adequate supply facilities for handling these inputs. Because of the high currents involved, transformers should be located as close to the welders as possible, keeping the secondary bus and feeder runs short. In many cases it will be found advantageous to use transformers containing a liquid that will not burn rather than oil in order that they can be located adjacent to the welding machines rather than at some relatively remote outdoor or vault location. With the load power factor generally falling between 20 and 40 per cent, it is essential that the reactance of the power supply system be kept at a minimum. Generous copper cross section in welding feeders is usually less important than proper spacing and arrangement of the conductors for minimum reactance.

The first question to be answered is: "For what voltage drop shall the supply system be designed?" No specific answer can be given which will apply to all cases and, as pointed out in the preceding report, satisfactory results may be obtained with 15 per cent regulation in one case and 5 per cent may be too much in another. However, in general with the usual class of production resistance welding involving low and medium carbon steels, satisfactory welding will result if the voltage drop to a point on the supply system common to two or more machines does not exceed ten per cent for the largest machine of the group. This statement is based on the assumption that there are relatively few large machines in the group being served (say, not over five or ten machines) and that, while two of them may occasionally operate at the same time, the chances of three or more operating together is extremely remote. Thus, if the machines are adjusted for perfect welding with a ten per cent voltage drop in their supply circuit, the welds will still be good when two machines operate together causing nearly 20 per cent drop. If three or more happen to hit together, poor welds or rejects may result. Care should be exercised in adjusting machines, with the setting made under highest voltage and maximum current conditions, just short of burning the weld so that under minimum voltage conditions a good weld will still result.

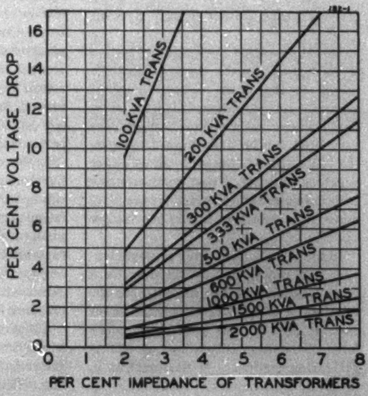

Figure 1. Welding supply—transformer regulation

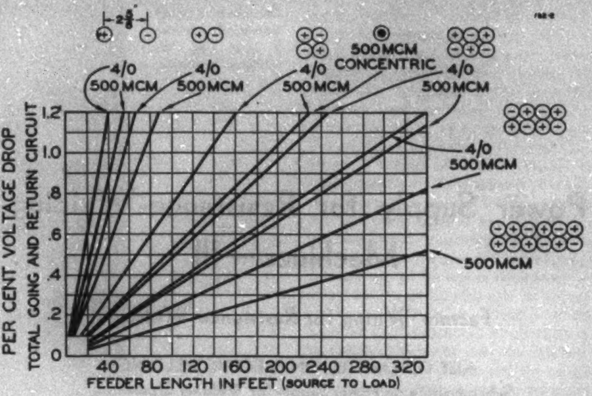

Figure 2. Welding supply—wire feeder regulation

Per cent voltage drop per 1,000 amperes of 30 per cent power factor, single-phase welding current

1. For 480-volt feeder, use chart values of per cent voltage drop
2. For 240-volt feeder, multiply per cent voltage drop by 2

Experience indicates that this general rule of ten per cent drop for the largest machine will result in a good workable installation in most cases although it should be realized there will be exceptions. The procedure outlined in the following sections will follow the ten-per-cent rule with some indication as to how to determine those installations which will require special consideration as exceptions to the general rule.

Where even less than ten per cent regulation can be provided at about equal cost, such as obtained by close spacing of feeders, this obviously should be done. The ten-per-cent figure is set only as an approximate allowable upper limit and any improvement below this value is all to the good and makes for that much better welding conditions.

Interlocking can be resorted to under some conditions to insure not more than one or two machines operating at the same time. This is an inexpensive practice where only a few large machines are involved and in most cases production speed is not materially reduced.

While the current-carrying capacity of the supply feeders and transformers must receive consideration, if provision is made to keep the voltage drop within the necessary limits, there usually will be sufficient attendant thermal or carrying capacity.

Voltage Drop

For convenience, the supply system can be broken up into three parts:

1. High-voltage power supply system (2,400 volts or higher)
2. Step-down transformer bank
3. Low-voltage bus or feeder (240 or 480 volts)

High-Voltage Power Supply System

The high-voltage power supply system in most cases is the power company's service to the plant. Where the plant generates its own power, it is typified by the generator bus system. In most cases very little can be done toward reducing the voltage drop in the high-voltage power supply system at a cost commensurate with the expenditure needed for the same percentage reduction in the low-voltage system.

In the case of service from a power company, the amount of voltage drop for a given welding load is dependent upon the relative location of the industrial plant with respect to the power company's large distribution substations as well as generating stations. If the plant is in an established industrial area served by large substations and not too far from large generating stations, the voltage drop in the high-voltage system will be a negligible factor. However, if the plant has been located in a rural or small-town area far removed from the power company's main generating stations, as is becoming more common under the present-day trend toward decentralization of industry in the search for low manufacturing costs and reduced taxes, the high-voltage system regulation may loom up as a very troublesome factor. Any plant in which resistance welding is extensively used should carefully investigate this matter of high-voltage system regulation when contemplating moving the plant to any other location with less adequate power facilities for welding.

In the case of private power generation, the voltage drop at the generator bus will be inversely proportional to the total rating of generators feeding the bus. The small and moderately sized plant will experience considerable difficulty in handling any but the smaller-sized welding machines without encountering lamp flicker problems in their plant and office lighting.

The first step in designing the plant wiring and bus layout for welding is to determine the high-voltage system regulation. This can be obtained from the local power company by giving them the maximum kilovolt-amperes and power factor that the largest machine will draw from the power system. Subtract the figure obtained from the total allowable ten per cent and the remainder is that which can be allowed in the step-down bank and secondary or low-voltage bus system. For instance, assume the largest welder is rated 300 kva and will deliver a maximum welding current of 100,000 amperes with a high secondary open circuit voltage of 8 volts. The approximate maximum kilovolt-ampere input (neglecting exciting current) is $(100,000 \times 8)/1,000 = 800$ kva. From the power company representative it is learned that 800 kva at an estimated 30 per cent power factor will cause four per cent drop in the power company service to the transformer bank at the customer. This subtracted from ten per cent leaves six per cent which can be used up in the step-down transformers and low-voltage bus system.

Step-Down Transformer Bank

On the assumption that the remaining allowable six per cent drop can be divided about equally between the step-down transformer bank and low-voltage bus system, it is necessary to select the proper size transformer which will limit the drop to about three per cent.

Welders can either be served from a single-phase transformer bank or a three-phase bank, and where the welding load is large enough to justify a separate transformer bank for welding load only, it will be found advantageous and more economical of capacity to use a single-phase system. The load is single phase and it will remain single phase no matter

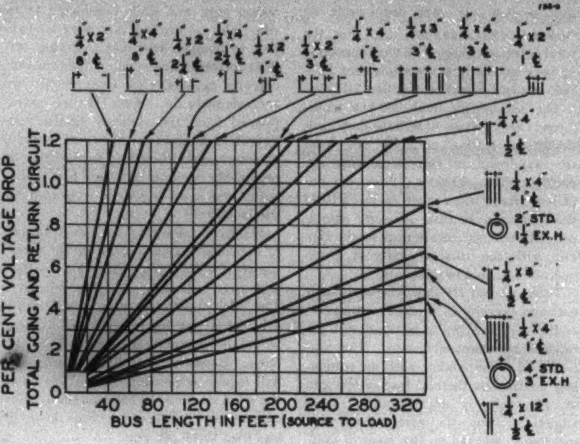

Figure 3. Welding supply—bus regulation

Per cent voltage drop per 1,000 amperes of 30 per cent power factor, single-phase welding current

1. For 480-volt bus, use chart values of per cent voltage drop
2. For 240-volt bus, multiply per cent voltage drop by 2

how the transformers ahead of it are connected. Sometimes it is desirable to spread the individual single-phase loads over the three-phase wires for more economical utilization of the supply lines, but unless there are large numbers of machines connected, the necessity for balancing the load is not important. When there are many machines, they are usually scattered around in different parts of the plant so that several step-down banks become necessary at different locations. In this case individual single-phase banks can be connected to separate phases and thus bring about some semblance of balance on the supply wires.

A given kva of single-phase load fed from a three-phase transformer bank will cause just twice as much transformer voltage drop as the same kva load fed from the same capacity in transformers connected as a single-phase bank. It is thus obvious that, where the transformer voltage drop must be kept at a minimum, it is highly desirable and more economical to use single-phase, step-down banks of transformers.

In case the welding load is relatively small in comparison with the motor and other power load of the plant, it can readily be served from the same three-phase bank serving the power load. Individual plant and service conditions thus dictate whether single-phase or three-phase banks are the logical selection. Irrespective of whether the welding load is served from single-phase transformers or from three-phase transformers in combination with the motor and power load, the lighting load should usually be handled separately in order to prevent flicker difficulties.

Figure 1 shows per cent voltage drop per 1,000 amperes of 30 per cent power factor welding current through transformer banks of different sizes and impedance. Plant practice may determine the size and impedance of individual transformers and the number of units to connect in parallel can be determined from the chart. For instance, assume that 300-kva, 3$^1/_2$-per-cent-impedance transformers are used by this particular plant in its step-down banks. A load of 800 kva represents 1,670 amperes at 480 volts. From figure 1: 1,670 amperes through a 300-kva, 3$^1/_2$-per-cent-impedance transformer causes 1.67 times 5.6 per cent = 9.4 per cent = voltage drop. Therefore, three transformers in parallel would have to be used to stay within the predetermined limit of three per cent drop. In some cases a special low-impedance transformer may be economically justified. For example, if a two-per-cent-impedance transformer is purchased, the nearest size transformer would be 500 kva which would allow 3.2 per cent drop. This might be cheaper than the three 300-kva transformers but would have the definite disadvantage of not being usable interchangeably at other plant locations. If a plant has sufficient welding load, it sometimes pays to standardize on special low-impedance transformers for welding only and not attempt to make them interchangeable with transformers used in power and lighting banks.

Low-Voltage Bus or Feeder

There is now only three per cent remaining out of the original allotted ten per cent drop. It is found that the bus or feeder must be 300 feet in length to reach the two machines located farthest from the transformer bank.

Figures 2 and 3 show the per cent voltage drop per 1,000 amperes of 30 per cent power factor welding current for different types and sizes of bus and wire construction. Figure 2 is for various wire arrangements and figure 3 for different bus arrangements. Some plant engineers prefer one class of construction and some the other. The bus can be made up on the job or it can be purchased, prefabricated in unit lengths either with or without enclosures.

Usually if the welders are in a fairly compact group but at some appreciable distance from the transformer bank, some arrangement of wire feeder works out to advantage. However, where the machines are scattered and frequent taps must be made to the supply wires or bus, a bus system is perhaps more advantageous in that frequent connections to it are readily made.

From the charts it is found that two 500,000-circ-mil wires per leg in conduit would handle 800 kva with 2.6 per cent drop at the 300-foot distance. (800 kva = 1,670 amperes. From the chart the drop for 150 feet = 0.78 per cent; for 300 feet and 1,670 amperes the voltage drop equals 0.78 per cent times 2 times 1.67 = 2.6 per cent.) For the bus construction a bus consisting of two $^1/_4$-inch by 4-inch copper bars on one-inch

Table I. Equivalent Continuous Loading of Typical Welding Machine Installations

Types of Welding	Equivalent Continuous Load Expressed in Per Cent of Sum of Name-Plate Ratings
Spot, projection, flash	5 to 10 (most installations) 10 to 20 (very few installations)
Hydromatic, butt	10 to 20
Seam	25 to 70

centers would be suitable from a voltage-drop standpoint.

It is possible that either of these selections may have sufficient current-carrying capacity for handling the equivalent steady or thermal load of the group of welders. However, if it is found that more carrying capacity is needed, other configurations are shown with equal or better voltage-drop characteristics.

Equivalent Continuous Thermal Loading

There are several ways in which the equivalent continuous thermal loading of a group of welders can be determined. It might be reasoned that the quickest and simplest method would be to add the name-plate kilovolt-ampere ratings of the individual welding transformers, and then apply a suitable diversity factor for group operation. The welding transformers are rated on a 50-per-cent duty-cycle basis and, consequently, if all of the machines are operated continuously right up to the thermal capacity of their transformers, the equivalent continuous thermal loading would be $\sqrt{0.50}$ or 70.7 per cent of the sum of the name-plate ratings. Thus, if there were ten 300-kva welders, the supply system on this basis should have a carrying capacity of 70.7 per cent of 3,000 kva, or 2,100 kva less the diversity factor correction.

In actual practice, however, most machines, except perhaps some seam welders, operate well below their maximum thermal capacity, because the size of transformer in the machine is dictated by the required welding current output rather than by thermal considerations.

Tests of many installations show that the values given in table I are more clearly representative of actual field conditions. Thus, if the machines are predominately spot, projection, or flash welders, a supply system with a rating of 15 per cent of the sum of the name-plate ratings of the machines would, in most cases, be adequate. Thus, taking the ten 300-kva welders, the supply system should be good for about 15 per cent of 3,000 kva, or 450 kva.

A second check should be made based upon the actual kilovolt-ampere loads of the welders and their operating duty cycles. Assume that each of the ten 300-kva machines was on a production schedule of 100 welds per hour with maximum loads of 800 kva for 10 cycles per weld. The corresponding duty cycle of each machine is: $(10\times100)/(60\times60\times60)=0.46$ per cent. The equivalent continuous load corresponding with 800 kva at 0.46 per cent duty cycle is: $\sqrt{0.0046}\times800$ kva $=54$ kva. For the total of ten machines, if all were operating at peak production, the equivalent kilovolt-amperes would be $10\times54=540$ kva.

The selection of three 300-kva transformers on the basis of voltage-drop considerations is thus perfectly safe from the standpoint of current-carrying capacity. The 500-kva, 2-per-cent-impedance transformer might be just a little small from a thermal capacity standpoint for ten machines in peak production but, with the usual diversity of group operation, should be adequate.

Tables II and III show the equivalent carrying capacity in continuous amperes of the various types of bus and wire arrangements commonly used. The ampere load corresponding with an equivalent continuous thermal load of 500 kva at 480 volts is approximately 1,000 amperes. Thus, the wire construction previously selected on the basis of voltage drop is not large enough from the standpoint of current-carrying capacity. A wire grouping consisting of four 500,000-circ-mil wires per leg (item 11, table II) is rated about 1,000 amperes and should be adequate for the job. This wire arrangement will have only 1.2 per cent voltage drop for an 800-kva load swing, thus being well within the three per cent allowed.

It should be emphasized here that the current-carrying capacities given in table II for six or more total wires in a trough or raceway enclosure are estimated values only and while considered to be reasonable approximations, they are subject to change whenever verifying test data become available. The current-carrying capacities for most of the bus arrangements in table III are extrapolated from test data of similar configurations both in the open and in metal enclosures and should, consequently, be reasonably accurate although here again, actual test data would be welcomed by the industry.

Similarly, table III shows several types of bus construction well within the three-per-cent voltage-drop allowance which will have adequate carrying capacity. The original selection of one $^1/_4$-inch by 4-inch bar per leg on one-inch centers would be adequate if mounted in the open. However, most bus installations will require enclosures and on this basis the selection would be between the heavier current-carrying busses having drops of less than three per cent.

Chance of Simultaneous Welds

Designing for a total of ten per cent voltage drop for the operation of the largest machine produces satisfactory welding conditions only when three or more machines do not happen to operate at the same instant. Based upon the general law of averages, the expectancy of simultaneous welds can be readily calculated. For the sake of simplicity, it is assumed that even if only a single

cycle of one weld overlaps another, this would constitute a simultaneous weld. Obviously, except for very short-time welds (two to three cycles), a single cycle overlap should not prove serious and this assumption thus introduces a considerable factor of safety.

T = total time per weld per machine, including "off" and loading time as well as actual weld time

t = actual weld time per machine

E = number of machines

$\frac{T}{tE} \times \frac{T}{t(E-1)}$ = interval in terms of number of welds between operations in which *two* machines make a weld at the same time including any slight overlapping of actual welding time

$\frac{T}{tE} \times \frac{T}{t(E-1)} \times \frac{T}{t(E-2)}$ = interval in terms of number of welds between operations in which *three* machines make a weld at the same time including any slight overlapping of welding time

In usual production welding if rejects due to simultaneous welds do not occur oftener than once per hour, which would be one weld out of every 5,000 or 10,000, conditions would probably be considered highly satisfactory. Table IV shows various combinations of machines, welding time, hourly production, and corresponding interval of time between expected simultaneous welds. For instance, 20 machines with three-cycle welding can produce 200 welds per hour per machine with an expectancy of three simultaneous welds and three rejects every 1.7 hours. With the production stepped up to 300 welds per hour per machine, the resultant expected interference might be such that it would be desirable to either split the machines into two groups or design for a five per cent instead of ten per cent voltage drop in the supply system.

The last column shows total time divided by the actual weld time of all large machines on the bus. As long as this value is greater than 10 or 20, satisfactory welding conditions should generally result on a supply system with ten per cent voltage drop, as the chances of three simultaneous welds occurring oftener than once per hour is rather remote. (For exceptions see last paragraph.) It should be remembered that these considerations apply only to the large machines. Innumerable small machines can be served from the same transformer bank and bus system along with the five or ten large machines, upon which the distribution system design is based, without any further consideration except that of thermal carrying capacity of the system.

It might not be amiss in this connection to point out another frequently encountered cause of poor welding in addition to that of excessive voltage regulation. There is a tendency on the part of many users of welding equipment to increase the welding speeds far beyond the capacity of the equipment to make good welds. As a result, a certain percentage of such welds are inferior. The designer then specifies a greater number of welds in an attempt to assure himself of a sufficient number of good welds to produce a satisfactory joint. The production department must then make these welds at an even faster rate of speed to maintain costs, resulting in an even greater number of inferior welds.

This vicious circle of events can be eliminated by insistence upon good welding throughout, resulting in fewer welds per joint, which in turn permits welding speeds commensurate with good welding. This results in better voltage regulation by reducing the chances of simultaneous or interfering welds on any given feeder line.

There may be some classes of welding where every weld must be perfect and there must be no chance of even a few undetected poor welds passing inspection. In these cases it may be desirable to design for closer regulation. However, even under these conditions, the extra investment needed for reduced regulation should be balanced against the cost of necessary recorders and indicators for detecting welds made under improper conditions of voltage, current, and time

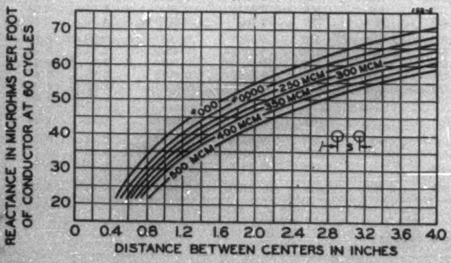

Figure 5. Reactance of standard strand cables at 60 cycles

It might be more economical to invest in the recorders and indicators than in excessive feeder and transformer capacity which would only be needed once or twice a day when three or more machines might happen to hit together.

Example. Ten 300-kva machines, each machine producing 100 welds per hour of 10 cycles duration each:

$$T=\frac{60\times 60\times 60}{100}=2{,}160 \text{ cycles}$$

$t=10$ cycles

$E=10$ machines

$$\frac{T}{tE}\times\frac{T}{t(E-1)}=\frac{2{,}160}{10\times 10}\times\frac{2{,}160}{10\times 9}=518 \text{ welds}$$

between operations in which *two* machines make a weld at the same time

Total output = 1,000 per hour

Two welds together every (518×60)/1,000 = 31 minutes

$$\frac{T}{tE}\times\frac{T}{t(E-1)}\times\frac{T}{t(E-2)}=\frac{2{,}160}{10\times 10}\times\frac{2{,}160}{10\times 9}\times\frac{2{,}160}{10\times 8}=14{,}000$$

welds between operations in which *three* machines make a weld at the same time

Three welds together every 14,000/1,000 = 14 hours

Total time divided by weld time of all welders = (60×60×60) / (10×10×100) = 21.6

Interlaced Bus Calculations

The reactance values of the various wire groupings and bus-bar configurations shown in figures 2 and 3 and in tables II and III were calculated by means of the following short-cut method, utilizing the charts of reactance for a pair of conductors (either for conductors, figure 4, or standard strand cables, figure 5).[1] In this way it is possible to calculate the reactance of an interlaced bus or cable system with a reasonable degree of accuracy in a few minutes, as compared with the more laborious method based upon the fundamental relations of mutual and self-inductance which at best requires several hours.

This short-cut method of calculation is incorporated as part of this report in order that quick calculations can be made for other wire or bus configurations than those shown in the tables.

The basic methods and curves used here are not new, but were published in U. S. Bureau of Standards Scientific Paper No. 281 by Francis B. Silsbee, and also in *The Electric Journal* of June 1919 in an article entitled "Reactance Values for Rectangular Conductors" by H. B. Dwight. However, it was felt desirable to bring together all of the necessary data for the calculation of welder bus reactance and to show by actual examples the use of these data for the calculation of interlaced conductors.

The more general types of welder busses which are commonly used are: (1) four or more stranded insulated conductors interlaced and clamped together, (2) interlaced copper bars, and (3) concentric tubes. Figures 4 and 5 show the total reactance, self minus mutual, between two conductors. The same curves can be used in the following manner when more than two conductors are involved and there is an even number of conductors. Consider an interlaced bus consisting of six conductors, three going and three returning, as shown in item 15, table III, arranged as follows:

(+1) (−4) (+2) (−5) (+3) (−6)

Since the average drop of the going circuit equals the average drop of the return circuit, it is only necessary to find the drop in the going circuit and multiply it by two to determine the total circuit drop. If, as a first approximation, it is assumed that the current divides evenly between all of the going conductors, the reactance of any going conductor is the sum of the reactances of all the return conductors to the given going conductor minus the reactance of the remaining two going conductors to the given going conductor. Dividing the sum of the reactances of the going conductors by three gives the average going reactance per conductor and dividing this average by three (since it is assumed that only one-third of the current went through each conductor) gives the going circuit reactance. Multiplying this value by two gives the total circuit (going plus return) reactance.

The reactance of each going conductor can be written as follows:

$$X_1=X_{14}+X_{15}+X_{16}-X_{12}-X_{13}$$
$$X_2=X_{24}+X_{25}+X_{26}-X_{21}-X_{23}$$
$$X_3=X_{34}+X_{35}+X_{36}-X_{31}-X_{32}$$

The total circuit reactance (going plus return) is:

$$X_T=\frac{2}{9}(X_1+X_2+X_3)$$

It should be pointed out that, although this method is approximate, it is ac-

*Note: On border line of unsatisfactory operating conditions if supply system is designed for ten per cent voltage drop for operation of largest machine. For these conditions supply system should probably be designed for about five per cent voltage drop.

curate within ten per cent which is good enough for most practical calculations.

Numerical Example 1. Determine the reactance of an interlaced bus 1,000 feet long, consisting of 1/4-inch by 4-inch copper bars spaced one-inch center-to-center as shown in table III, item 15. The distance between the center lines of each conductor and all of the other conductors should be calculated and the reactances corresponding to these distances should be obtained from figure 4.

For example, the distance between the center lines of conductors 1 and 4 is $1'' \times \frac{S}{a+b} = \frac{1''}{{}^1/_4{}'' + 4''} = 0.235$ and the corresponding reactance is 0.0125 ohm per 1,000 feet. The remaining reactances can be found in a similar manner.

$$X_1 = 0.0125 + 0.0290 + 0.0392 - 0.0220 - 0.0347 = 0.0240$$

$$X_2 = 0.0125 + 0.0125 + 0.0290 - 0.0220 - 0.0220 = 0.0100$$

$$X_3 = 0.0290 + 0.0125 + 0.0125 - 0.0347 - 0.0125 = -0.0027$$

$$X_T = \frac{2}{9}(X_1 + X_2 + X_3) = \frac{2}{9}(0.0249 + 0.0100 - 0.0027) = 0.00696 \text{ ohm (going and return)}$$

The same method can be used on stranded cables, except that the reactance values are taken from figure 5.

Numerical Example 2. Determine the reactance of six 250,000-circ-mil interlaced standard-strand, rubber-insulated cables 1,000 feet long and arranged similar to item 8, table II, arranged as follows:

(+1) (−4) (+2)
(−6) (+3) (−5)

The copper diameter is 0.576 inch, the rubber thickness is 0.094 inch, and the braid thickness is 0.020 inch, giving a total diameter of 0.804 inch. The distance between the center lines of each conductor and all of the other conductors should be calculated and the corresponding reactances should be obtained from figure 5.

The distance between the center lines of conductors 1 and 3 is $\sqrt{0.804''+0.804''} =$ 1.138 inches and the corresponding reactance is 0.0368 ohm per 1,000 feet. The remaining reactances can be found in a similar manner.

$$X_1 = 0.0288 + 0.0288 + 0.0473 - 0.0448 - 0.0368 = 0.0233$$

$$X_2 = 0.0288 + 0.0473 + 0.0288 - 0.0448 - 0.0368 = 0.0233$$

$$X_3 = 0.0288 + 0.0288 + 0.0288 - 0.0368 - 0.0368 = 0.0128$$

$$X_T = \frac{2}{9}(X_1 + X_2 + X_3) = \frac{2}{9}(0.0233 + 0.0233 + 0.0128) = 0.0132 \text{ ohm (going and return)}$$

The reactance of concentric tubular busses is easily expressible in a formula. Let the outer radius of the outer tube be r_4, the inner radius of the outer tube be r_3, the outer radius of the inner tube be r_2, and the inner radius of the inner tube be r_1. The reactance then can be expressed as:

$$X = 11.49 \; 4.606\left(\log_{10}\frac{r_3}{r_2} + \frac{r_1^4}{(r_2^2-r_1^2)^2}\log_{10}\frac{r_2}{r_1} + \frac{r_4^4}{(r_4^2-r_3^2)^2}\log_{10}\frac{r_4}{r_3}\right) - \left.\frac{r_2^2+r_1^2}{2(r_2^2-r_1^2)} - \frac{r_4^2+r_3^2}{2(r_4^2-r_3^2)}\right] \times 10^{-3}$$

where X is in ohms per 1,000 feet of bus (total going and return circuit)

Feeder Data for Small Installations

In cases of small installations of welders served at low voltage (240 or 480 volts) by the power company the plant wiring will generally consist of wires pulled in conduit. It is usually unnecessary to lace the going and return wires together for minimum spacing before pulling in conduit, as the natural positioning of the wires in the conduit will give close enough spacing.

Table V gives the impedances of circuits and current-carrying capacities of relatively small wires suitable for small installations.

TYPICAL EXAMPLES

Example 1. Small Job-Welding Shop

Machines:
One 150-kva seam welder
Four 20-kva spot welders

Maximum kilovolt-ampere load swing of largest machine:
1,500 amperes at 240 volts = 360 kva

Table V.—Impedance and Carrying Capacity of Conductors in One Conduit

Wire Size	Conduit Size (Inches)	Resistance One Conductor Per 1,000 Feet (Ohm)	Reactance One Conductor Per 1,000 Feet (Ohm)	Current-Carrying Capacity (Amperes) Copper, 60 Deg C Ambient, 30 Deg C
2	1¼	0.156	0.040	107
0	1½	0.098	0.041	139
2/0	2	0.078	0.038	160
3/0	2	0.062	0.036	182
4/0	2	0.049	0.038	210

Regulation for 360 kva:	Per Cent
1. Supply system (4,800 volts)	3.0
2. 200-kva, single-phase, 4,800/240-volt, 3-per-cent, *Z* transformer	5.5
3. 100 feet two 4/0 wires per leg in conduit	2.3
Total	10.8

Equivalent continuous thermal loading:
0.7×150 kva =105
0.1×4×20 kva= 8
113 kva=470 amperes at 240 volts

Example 2. Small Job-Welding Shop

Machines:
Three 50-kva spot welders
Two 150-kva press welders
One 200-kva projection welder

Maximum kilovolt-ampere load swing of largest machine:
2,100 amperes at 240 volts=500 kva

Regulation for 500 kva:	Per Cent
1. Supply system (4,800 volts)	4.1
2. 500-kva, single-phase, 4,800/240-volt, 3-per-cent, *Z* transformer	2.9
3. 150 feet one $^1/_4$-inch by 4-inch bar per leg, 1-inch centers	3.7
Total	10.6

Equivalent continuous thermal loading:
10 per cent×650 kva=65 kva=270 amperes at 240 volts

Example 3. Small Manufacturing Plant

Machines:
Five 250-kva press welders
Two 50-kva spot welders
Eight 30-kva spot welders

Maximum kilovolt-ampere load swing of largest machine:
825 amperes at 485 volts=400 kva

Regulation for 400 kva:	Per Cent
1. Supply system (24,000 volts)	1.1
2. 700-kva, single-phase, 24,000/485-volt, 13-per-cent, *Z* transformers	7.4
3. 150 feet one $^1/_4$-inch by 2-inch bar per leg, $2^1/_4$-inch centers	2.0
Total	10.5

Equivalent continuous thermal loading:
Practically all three-cycle welding so use about five per cent of sum of connected load 0.05×1,590 kva=80 kva=165 amperes at 485 volts

Example 4. Small Manufacturing Plant

Machines:
Two 150-kva projection welders (automatic feed)
One 75-kva spot welder
One 50-kva spot welder
Eleven 25-kva portable welders

Maximum kilovolt-ampere load swing of largest machine:
850 amperes at 240 volts=205 kva

Regulation for 205 kva:	Per Cent
1. Supply system (4,800 volts)	2.7
2. 600-kva, three-phase, 4,800/240-volt, 5-per-cent, *Z* power transformer bank	3.4
3. 170 feet two 4/0 wires per leg in conduit	2.6
Total	8.7

Equivalent continuous thermal loading:
150-kva projection welder
2,000 welds per hour—3-cycle welds
Duty cycle=(2,000×3)/(60×60×60)=2.77 per cent
200 kva at 2.77 per cent duty cycle=34 kva continuous
Two machines=2×34=68 kva continuous
Remaining machines, 10 per cent×400=40 kva
Total, 108 kva

Example 5. Large Manufacturing Plant

Location *A*. Connect to Phase *AB*

Machines:
Three 550-kva butt welders
One 500-kva projection welder
One 400-kva projection welder
Three 150-kva projection welders

Maximum kilovolt-ampere load swing of largest machine:
2,700 amperes at 480 volts=1,300 kva

Regulation for 1,300 kva:	Per Cent
1. Supply system (4,800 volts)	5.6
2. Three 500-kva, single-phase, 4,800/480-volt, $3^1/_2$-per-cent, *Z* transformers	3.0
3. 125 feet two $^1/_4$-inch by 4-inch bars per leg, interlaced $2^1/_4$-inch centers	1.7
Total	10.3

Equivalent continuous thermal loading:
550-kva butt welder
200 welds per hour—30-cycle welds
Duty cycle=(200×30)/(60×60×60)=2.77 per cent
1,300 kva at 2.77 per cent duty cycle=216 kva continuous
Three machines=3×216=648 kva continuous
Remaining machines, 10 per cent × 1,350=135 kva
Total, 783 kva=1,670 amperes at 480 volts

Location *B*. Connect to Phase *BC*

Machines:
40 hydromatic welders, 150 to 300 kva each
Total connected load=7,000 kva

Maximum kilovolt-ampere load swing of largest machine:
2,100 amperes at 480 volts=1,000 kva

Regulation for 1,000 kva:	Per Cent
1. Supply system (4,800 volts)	4.1
2. Two 500-kva, single-phase, 4,800/480-volt, $3^1/_2$-per-cent, *Z* transformers	3.5
3. 200 feet two $^1/_4$-inch by 4-inch bars per leg, interlaced $2^1/_4$-inch centers	1.9
Total	9.5

Equivalent continuous thermal loading:
15 per cent×7,000 kva=1,050 kva=2,200 amperes at 480 volts

Location *C*. Connect to Phase *CA*

Machines:
Two 700-kva butt welders
Two 500-kva butt welders

Maximum kilovolt-ampere load swing of largest machine:
3,500 amperes at 480 volts=1,670 kva

Regulation for 1,670 kva:	Per Cent
1. Supply system (4,800 volts)	6.9
2. Three 500-kva, single-phase, 4,800/480-volt, $3^1/_2$-per-cent, *Z* transformers	4.0
3. 150 feet two double $^1/_4$-inch by 3-inch bars per leg, interlaced 3-inch centers	3.1
Total	14.0

The two 700-kva machines were interlocked so that they could not be operated together and the two 500-kva machines were also interlocked.

Equivalent continuous thermal loading:
700-kva welder
100 welds per hour—$2^1/_2$ second welds
Duty cycle=(100×$2^1/_2$×60)/(60×60×60)=6.95 per cent
1,670 kva at 6.95 per cent duty cycle=440 kva
Two machines=2×440=880 kva
500-kva welder
100 welds per hour—2 second welds
Duty cycle=(100×2×60)/(60×60×60)=5.55 per cent
1,200 kva at 5.55 per cent duty cycle=283 kva
Two machines=2×283=566 kva
Total, 880+566=1,446 kva

A Conserved-Pressure Air-Blast Circuit Breaker for High-Voltage Service

W. R. RANKIN
NONMEMBER AIEE

R. M. BENNETT
ASSOCIATE AIEE

Synopsis: This paper describes the design and construction of a 138-kv, 1,500,000-kva air-blast circuit breaker. The construction is made possible by the use of a new interrupting device which utilizes the axial blast nozzle together with a "conserved pressure" chamber. The chamber receives the exhaust from the interrupting nozzle and contains the movable contact of the breaker in its open position. By means of a spring-loaded relief valve the pressure and dielectric strength of the air in the chamber are maintained at a high level.

The pressure in the chamber is at the same time less than 50 per cent of the pressure above the nozzle restriction so that the air flow through the interrupting nozzle is unimpaired, being the same as through the same nozzle discharging to atmospheric pressure. As a consequence, the conserved pressure breaker is found to have the same ability to interrupt current as a conventional axial nozzle but to be capable of interrupting circuits of much higher voltage.

The 138-kv three-phase breaker consists of two interrupting units in series per pole with a disconnecting device included as part of the breaker. Operation of the breaker is entirely pneumatic, opening and closing being performed by energizing the electrically operated valve.

Interrupting Unit

TWO distinct types of air-blast interrupting units have previously been described, the cross blast,[1,2,4] in which air is directed across the arc formed in the path of the separating contacts, and the axial blast in which air flows through an orifice in the direction of the moving contacts.

Data[1] published at the 1940 midwinter convention showed that the European axial blast unit required a volume of air for interruption that was proportional to the maximum current interrupted. As a consequence such a breaker would require excessive quantities of air if it were built in the ratings found in this country. The problem of interrupting these high currents, of as much as 100,000 amperes, was solved by the introduction of the cross-blast unit which makes very economical use of air.

For high-voltage service, however, the currents to be interrupted are relatively light and the interruption problem is one of voltage magnitude. Under these conditions, the axial nozzle shows more promise for it is naturally a better insulating structure than the cross-blast breaker. Since it is cylindrical it may be turned from a solid piece of insulating material and it can be readily accommodated inside of a porcelain insulator.

However, the straight axial nozzle was found to have limited voltage-interrupting capacity and it was through a study of these limits that the conserved pressure interrupter was developed. The conserved pressure breaker is a solution to the problem of interrupting relatively light currents at high voltage. Its development and a direct comparison between it and two axial nozzles will be described.

A simple form of the axial-blast interrupting unit which has been used in Europe is illustrated by figure 1. In this design high-pressure air flows around the cylindrical stationary contact and expands to the atmosphere through the nozzle from which the moving contact has been withdrawn. The moving contact is drawn out into the open air and in the fully open position comes to rest in a region of atmospheric pressure.

Figure 2 illustrates the variation of the dielectric strength of air as a function of pressure. As a consequence of this variation, the dielectric strength of the air at the fixed contact of the breaker is five or six times as great as at the moving contact whereas, depending upon the interrupter configuration, the voltage gradient in the low-pressure area may be as high as in the high-pressure region. As the voltage rises, after the current has been momentarily interrupted by the air blast, the moving contact then provides a starting point for an electrical breakdown between the contacts.

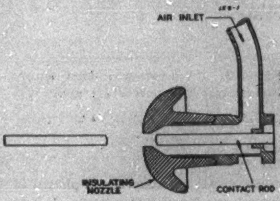

Figure 1. European high-voltage air-blast nozzle

This dielectric breakdown between the contacts can be avoided by a nozzle configuration of the type shown in figure 3*A*. Such a nozzle extends the region of high pressure—high dielectric-strength air to such a length that the contact spacing can withstand a high-applied voltage in spite of the fact that the air at the end of the moving contact is overstressed.

The interrupting ability of this long

nozzle, in kilovolt-amperes, is plotted in figure 4 as a function of voltage. It is to be noted that although the breaker can interrupt a relatively large kilovolt-ampere at 38 kv, it has a definite current limit, so that, at lower voltages, where a larger current must be interrupted for a given kilovolt-ampere, the breaker fails. That is, the large volumes of ionized gas produced by large currents cannot be discharged by the long-restricted nozzle with sufficient rapidity to permit interruption.

The nozzle of figure 3*B* represents another extreme. It consists of little more than an orifice and is consequently capable of interrupting considerable current at low voltage. See figure 4. However, after interruption of the current at high voltages, progressive dielectric breakdown proceeds from the overstressed air at the tip of the moving contact back toward the orifice to such an extent that the high-pressure air becomes overstressed and it too breaks down.

These difficulties were overcome by the conserved pressure design which permits the moving contact to remain in a region of high-pressure air after the contacts have separated.

Figure 5 is a schematic representation of the breaker. High-pressure air is supplied from below, flows around the stationary contact and expands through an orifice to a chamber surrounding the moving contact. Pressure in this chamber is maintained at approximately 100 pounds per square inch by means of a spring-loaded relief valve. Provided the pressure in the chamber does not rise above approximately 53 per cent of the pressure above the orifice, the velocity and density of the air blast are unaffected by the pressure. It would therefore be expected that the performance of the conserved pressure breaker would be similar to that of the short orifice with the exception that it could interrupt much higher voltages. The dashed curve of figure 4 confirms this fact.

Breaker Construction

Each phase of the 138-kv air-blast circuit breaker consists of two conserved pressure-type interrupting units in series. The breaker which is rated 1,500,000 kva is supplied with air at 350 pounds per square inch.

The schematic drawing figure 6 shows the general arrangement of a single pole of the breaker. See figure 7. The essential parts consist of a main-blast valve for admitting air to the interrupters, an interrupting unit, a disconnect, and a mechanism for operating the disconnect.

The three-phase breaker has a main-air blast valve for each phase of the breaker. These are of the same type as the valves used in the 15-kv air-blast breakers described by Messrs. Strang and Boisseau at the 1940 midwinter AIEE convention.[3] They are poppet-type valves actuated by a piston which in turn is operated by air from a solenoid-operated differential pilot valve. The valves have an over-all operating time of two cycles from the time the solenoid coil is energized until the valve is completely open.

The interrupting contacts are separated by the action of the main air blast and are returned to the closed position by springs as soon as the air blast is turned off. Consequently a disconnect is provided, the function of which is to provide a clear air break after interruption is complete and before the interrupting contacts return to their closed position.

Closing of the breaker is performed by closing the disconnect. The closing speed of the breaker is not materially affected by current magnitudes in excess of the minimum breaker rating. This is accounted for by the fact that in the 138-kv breaker, the maximum rated current is a relatively light 9,500 amperes so that the magnetic forces are small compared with the inertia of the disconnect assembly.

The interrupting units are entirely pneumatic in operation, and require no mechanical connection with ground. The main air blast acts on a piston which is integral with the moving contact to move the upper contact upward separating the contacts.

When the movable contact has been withdrawn from the nozzle restriction the air blast which follows sweeps the contact space free of ionized gas at a current zero. The 138-kv breaker uses two interrupters in series, the total contact motion of each being eight inches. The interrupting contacts are returned by springs to the closed position as soon as the blast valve closes.

The interrupting nozzle is turned from a block of insulating material similar to fiber in possessing the property of becoming volatile at moderate temperatures. In the presence of an arc this property prevents the deposit of carbon on the surface of the nozzle and at the same time the gas which is evolved prevents the nozzle surface from reaching the high temperatures at which many otherwise

good insulators become conductors. The nozzle is contained in a herkolite tube which supports the upper contact piston and the conserved pressure-relief valve. The tube in turn is contained in a porcelain insulator.

The disconnect is also supported by a porcelain insulator which was specially developed for the purpose. The porcelain instead of having a straight creepage path inside, requiring that it be oil-filled and sealed, is made of a number of sections fused together. Each section is shaped like a cylinder closed at one end. When the sections are stacked up to form the insulator the closed ends of the sections become solid partitions across the inside of the insulator.

The disconnect arm engages long sliding stationary contacts by means of a

loose-hinged blade which twists as it disengages. The contacts are so shaped that the arc formed during closing burns heavy contact tips rather than the contact surfaces. Both opening and closing of the disconnect is performed by a double-ended pneumatic piston which acts to rotate, about a vertical axis, the whole assembly, consisting of disconnect arm and insulator.

Air Auxiliaries

Air is supplied to the breaker tank from a conventional electric motor-driven storage and compressor unit. To eliminate the possibility of moisture reaching the breaker a compression cycle is used to dry the air.

Air is compressed to 1,000 pounds per square inch, cooled so that moisture is condensed in the high-pressure chamber, and is expanded to 350 pounds per square inch. After expansion the dew point of the air is approximately 80 degrees Fahrenheit below the temperature of the ambient air.

The control for the expansion valves is by means of Bourdon-type pressure switches. The control is arranged so that no air expands from the 1,000-pound tank to the 350-pound tank unless the compressor has brought the high-pressure tank up to full pressure. Thus no air can flow into the 350-pound tank unless it has gone through the complete compression cycle.

Operation

A breaker-opening operation is performed by electrically energizing the three-blast valve solenoids in parallel. The three valves are pneumatically interconnected so that all three main blast valves can be opened by any one of the solenoid-operated pilot valves. Opening of the blast valves initiates two functions. First, an air blast is supplied to the interrupting units to separate the contacts and interrupt the arc. Second, air is supplied to the disconnect control to initiate opening of the disconnects. The disconnect control is pneumatically interlocked with the blast valves so that the disconnect cannot operate unless all three blast valves have opened. If all three blast valves open, air is admitted to a differentially-operated pilot valve which in turn admits air directly from the tank to the disconnect operating piston. Separation of the disconnect contacts is timed to take place after the arc has been interrupted. Once the opening operation has been initiated the closing control solenoid is electrically disconnected. Electrical control is also provided so that the disconnect operation can be prevented.

A Bourdon-type pressure switch is used to open both the electrical opening and closing circuits in case the tank pressure is below the safe operating limit. Breaker closing is performed by electrically energizing a valve which admits air to the closing side of the disconnect operating piston.

Rapid reclosing is provided as indicated by figure 9. The disconnect opening pilot valve is a three-way valve which in the energized position admits air from the tank through a dump valve to the opening side of the operating piston. A light spring together with air flowing through the dump valve in the direction of the operating cylinder holds the dump valve closed.

When the pilot valve is de-energized, however, it opens a passage, from the back of the dump valve to the atmosphere, permitting the dump valve to open and exhaust the air from the opening side of the disconnect operating piston. Trip-free operation is provided by using the same valve arrangement for the closing side of the disconnect.

A complete closing-opening operation of the breaker takes place in the following order. Starting with the interrupting contacts closed and the disconnect open,

1. Disconnect solenoid energized.
2. Disconnect closes.
3. Disconnect solenoid de-energized.
4. Blast-valve solenoid energized.
5. Blast valve opens.
6. Disconnect opening pilot energized by air blast.
7. Interrupting contacts parted by air blast and arc interrupted.
8. Disconnect opens.
9. Blast valve de-energized.
10. Interrupting contacts return to closed position.

A New Air Circuit Breaker With 250,000-Kva Interrupting Capacity

R. C. DICKINSON
ASSOCIATE AIEE

R. H. NAU
ASSOCIATE AIEE

Synopsis: Heretofore it has not been commercially feasible to apply air-type breakers of the 5,000-volt class to circuits capable of producing short-circuit currents equivalent to 250,000 kva. However the continued demand for air circuit breakers of higher interrupting ratings has stimulated the development of a new breaker suitable for these applications. This achievement has been accomplished through magnetically enhanced diffusion of ionized particles, establishing dielectric strength in a gaseous region which was previously highly conducting. The interrupter consists essentially of an arc chamber of laterally spaced refractory plates embodying V-shaped slots and a magnetic circuit which imposes an intense magnetic field transverse to the slotted plates during the arcing period.

The theory of arc interruption by this new air breaker is considered. Design details are described and illustrated. Complete sets of test results are given, with representative oscillograms. The test results are discussed, and it is demonstrated that the new breaker is applicable to modern metal-clad switchgear.

I. Introduction

THE advantages of air-type power switching equipment are becoming increasingly apparent to the electrical industry. The result is a general desire to be able to supply air circuit breakers over the entire range of applications which have become established by the use of oil-type switching equipment. In response to the demand to fill in the gaps in the established interrupting ratings with air circuit breakers, a new self-contained unit suitable for an interrupting rating of 250,000 kva at five kv has been developed.

Early in 1938 development of principles somewhat different from those of the original "De-ion" air breakers[1] resulted in devices having very high-current interrupting ability at moderate voltages.[2] Currents as high as 120,000 amperes at 750 volts were interrupted. The principle of operation is a combination of arc construction and rapid gas motion. The gas motion is produced by virtue of a self-induced magnetic field which imparts a net upward component of velocity to the conducting electrons. The arcing time is definitely limited to one-half cycle or less.

The scope of this principle of magnetic deionization was expanded to devices having 150,000-kva interrupting ratings at 2,500 and 5,000 volts.[3] Continuation of the development has resulted in still further application of magnetically enhanced diffusion of ionized particles. The following sections are devoted to describing the newly developed air circuit breaker having an interrupting rating of 250,000 kva at 4,000 to 5,000 volts.

II. Design of the Interrupter

In addition to meeting the current carrying and interrupting requirements, an air circuit breaker should have a space factor comparable to the similarly rated oil breaker. The problem is then one of suitably drawing and enclosing the arc and controlling the ionized gases and other by-products of arc interruption. It has been found that definite advantages exist in utilizing a relatively short arc and permitting the current of the arc in interruption to go to its normal zero in cycle—whereat intensive deionization is provided to establish dielectric strength. The method of magnetic deionization possesses this type of arc characteristic.[3]

An extended series of tests, table I, made on a standard 150,000-kva 5,000-volt breaker demonstrated that there was a wide margin of safety above the 150,000-kva rating. Hence the logical program was to continue development of this design.

It had been indicated that the voltage which could be interrupted was very nearly proportional to the number of refractory plates in the arc chamber. Further, the amount of current that could be interrupted was a function of the plate width and thickness and of the vent space between the plates. Hence for the five-kilovolt ratings, two refractory sections or twice the number of insulating plates were necessary. In order to bring the arc uniformly into the V-shaped slots of all the plates the structure was supported at sufficient height above the arcing contacts to permit the use of sloping arc horns. See figure 1. The added arc length and distance of arc travel required greater venting to exhaust and deionize the hot gases. The vents between the refractory plates were made more effective by using wider and longer plates and by stacking them farther apart. A space was provided intermediate to the two refractory sections to release the initial gas pressure and to stabilize the arc during current interruption. Figure 2 is a picture of the two sections of refractory plates taken from a 250,000-kva 5-kv arc chamber.

During short-circuit operation of the magnetic "De-ion" breaker an arc is drawn between the separating arcing contacts, and is looped upward, magnetically, into the V-shaped slots. By transfer of the arc to the panel-end horn (figure 1),

Interrupting Tests

The 138-kv, 1,500,000-kva breaker is required to interrupt 6,300 amperes at rated voltage which is approximately 80 kv line to neutral. The maximum current rating is 9,500 amperes.

Table I is a series of single-phase interrupting tests performed on a single pole of the breaker. The currents interrupted range from light currents, similar to line-charging currents, to a maximum of 10,700 amperes.

Rates of rise of recovery voltage up to 4,500 volts per microsecond have been interrupted at 132 kv.

Figure 8 is a magnetic oscillogram of the closing-opening operation of test number 30.

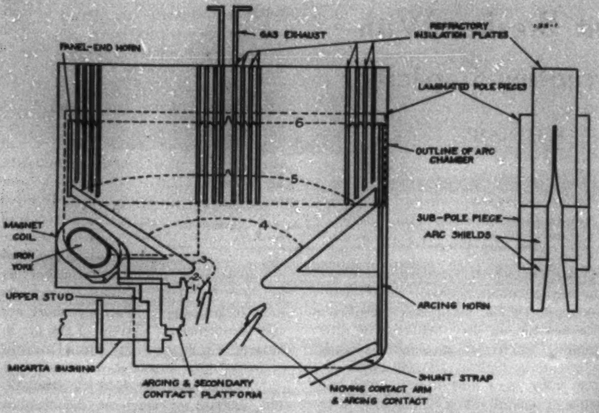

Figure 1. A diagrammatic sketch showing partial sections of the 5,000-volt magnetic "De-ion" interrupter. The dotted lines 1, 2, 3, 4, 5, and 6 indicate progressive positions in arc interruption

the magnet coil is switched into the circuit, thus imposing a strong transverse magnetic field. The upward motion of the arc is impeded by the refractory plates; however, a net upward component of velocity is imparted to the conducting electrons. They in turn bombard gas particles and produce a rapid flow of gas perpendicular to the arc. This reaction enhances the diffusion of the ionized gas particles and continuously causes the arc to ionize fresh gas in considerable quantities. The deionizing action is particularly prevalent near the edges of plates, and it continues in a sufficient degree to establish high dielectric strength during the period of relative low recovery voltage following a current zero.

By this method of magnetically enhanced diffusion of ionized gas particles the effectiveness and life of the interrupter are preserved. The long series of tests listed in tables II and III are typical runs which have not produced excessive wear on either the arc chamber plates or breaker contacts.

III. The Breaker Mechanism

The contact system and electromagnetic operating mechanism of the magnetic "De-ion" breakers are specially designed for high speed. Fast operation promotes both better contact protection and one-half cycle arcing time for currents of short-circuit values. Low inertia of the movable contact is obtained by a pivotally mounted contact arm upon which a pair of secondary and arcing contacts are rigidly attached to protect the main contact member. This main contact member is a solid copper block having heavy silver-inlay contacts. The arcing and secondary contacts are a silver-tungsten cintered mixture which is highly resistant to arcing. Figure 3 is a picture of a beaker with its contacts in open position.

A standard three-pole 5,000-volt breaker is shown in figure 4. The barrier structure is a plain interphase arrangement pivotally mounted as a unit at the

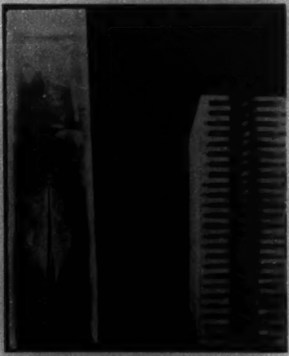

Figure 2. Two ceramic sections taken from an arc chamber after a series of 19 interrupting tests at 3,830 volts restored, single phase, and currents equivalent to 192,000 to 306,000 kva three phase

lower front corner. The unit is simply removed by pulling the top forward and lifting the assembly from its pivots.

The arc chambers are removable units supported by the laminated pole pieces. An individual chute assembly is shown in figure 5. The connectors of the arcing horns are automatically engaged when the arc chamber is pushed back into position on the laminated pole pieces.

The trip-free operating mechanism is mounted in a horizontal position immediately below the lower studs and moving contacts. It is isolated from the live parts by a steel barrier, and actuates the contacts through suitable insulating push rods. See figure 3.

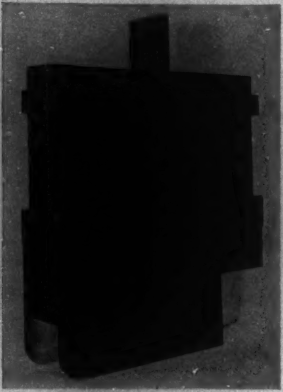

Figure 5. The arc-chamber unit of a magnetic "De-ion" breaker

An air dashpot is directly coupled to the operating lever of the mechanism. The volume of air handled is sufficient to absorb the kinetic energy of the opening contacts at both no-load and short-circuit capacity, thus bringing the contacts to a gentle rest without impairing the opening speed for approximately 50 per cent of the contact travel. The air dashpot is clearly shown in figure 4.

The magnetic "De-ion" breaker is designed to meet the requirements of modern metal-clad switchgear. Figure 6 illustrates the standard arrangement of the entire line of magnetic "De-ion" breakers for 2.5 to 5 kv, 600 to 2,000 amperes and up to 250,000-kva interrupting rating at 5 kv. The width of the 100,000- and 150,000-kva 3-pole breakers is 21³/₈ inches, and that of the 250,000-kva 5-kv unit is 31 inches.

IV. Test Results

Extended series of tests were made during the development of the 250,000-kva 5-kv magnetic "De-ion" breaker. In addition to demonstrating ample margin for an interrupting rating of 250,000-kva at 5 kv, these numerous tests have shown the continued effectiveness of the breaker when applied to repetitious duty at and above the interrupting rating. Indeed, the wear on the contacts and arc chamber parts is small even after many operations, and the functioning of the breaker is in no way impaired.

Table I illustrates a typical run of 49 consecutive interrupting tests made on a single pole of a 5-kv 150,000-kva breaker without service to the breaker or arc chamber. The short-circuit values ranged from load currents to 37,000 amperes (equivalent to 291,000 kva, 3-phase). Figure 7 is a picture of five oscillograms taken from the tests listed in table I.

A short run of 19 interrupting tests with currents as high as 306,000 kva is indicated in table II. Figure 8 shows representative oscillograms from the group. These tests were made on a 5-kv 250,000-kva breaker, causing very little wear upon the arc chamber parts. The two individual ceramic sections of this chute are shown in figure 2.

A series of 34 short-circuit tests were made on a similar 5-kv 250,000-kva arc chamber. These tests are listed in table III, and the starred data are illustrated by the oscillograms of figure 9. The data indicate considerable margin above the interrupting rating of 250,000 kva.

17	4,300	26.4	3/4	197
18	4,300	27.4	1/2−	204
19*	4,300	25.9	1/2−	193

*Oscillograms of these tests are shown in figure 8.

During another series of tests on a single pole of a 5-kv 250,000-kva breaker two consecutive shots of 300,000 kva 3-phase were obtained. The severity of these interruptions did not stress the interrupter unduly. The oscillograms are shown in figure 10.

Numerous interrupting tests have been made at lower current values with five kilovolts across a single pole. These low currents were obtained by connecting an air-cored reactor of negligible resistance directly in series with the breaker and a 20,000-kva generator. At 1.6 amperes the arc was interrupted in less than one-half cycle. The arcing time-current characteristic rises gradually to about 22 cycles at 14 to 20 amperes and recedes to 4 cycles at 600 amperes. At currents above several thousand amperes the arcing time is only one-half cycle.

The magnetic "De-ion" breaker is applicable to circuits requiring repetitious switching. No-load *CO* life tests have been made in excess of 25,000 operations without repair to any part. At the close of the tests there was no indication of wear or strain on the breaker which would require overhauling or replacement of any major item.

V. Conclusions

Magnetic Fields in Watt-Hour Meters

Effects of Wave Form on the Registration of Single-Phase Watt-Hour Meters

NONMEMBER AIEE

Synopsis: The growing use of electrical equipment which causes distortion in the supply voltage and current has caused increased concern regarding the performance of watt-hour meters used to meter the energy required by such equipment. The watt-hour meter is designed and adjusted, in practice, to operate on practically distortionless current and voltage.

An analysis of the factors involved and an experimental study of meter registration under definitely controlled conditions show that watt-hour meters should perform satisfactorily unless the degree of distortion is large. These controlled conditions included wide variations in the distortion of potential and current both individually and together. The characteristics of meters of recent design, of all the major manufacturers, were studied experimentally.

Introduction

THIS study of the effects of variation in wave form on the registration of a watt-hour meter is a part of a general study of the magnetic conditions which exist in such meters during their operation. Data which are presented for illustration of these effects are to be considered more qualitatively than quantitatively since they apply directly to particular types of meters of recent design. The order of magnitude of the effects of variations in wave form can be inferred in any case except perhaps for meters of very early design.

Single-phase meters only are considered here. The influence of the interaction of the several elements of polyphase meters is to complicate relationships introduced by a variation in wave form and depends upon the position of the elements relative to each other. Since the general effect of harmonics is found to be small, the relatively small influence of one element on another in a multidisk meter should give rise to effects of but minor importance so far as they are caused by harmonics.

Because of the necessary differences between the designs of elements of multidisk and single-disk polyphase meters, the effects of wave-form variations on the performance of single-disk meters are being given separate study.

Meters of recent designs, although made by various manufacturers are much more nearly alike, fundamentally, in their magnetic circuits than those formerly manufactured. Many differences in detail are still present and although the net result is, in each case, a meter with satisfactory performance characteristics, variations may be noted in the performances of the meters when used in circuits where abnormal wave forms occur in voltage or current.

In addition to differences in the proportions of parts of the magnetic circuits of the meters, design details which influence the flux distribution and variation in a meter and consequently the performance characteristics under abnormal loads are the lagging circuit and the compensations for friction, temperature change, and overload. No attempt is made to evaluate separately the influence of each component part, their collective influence only being noted. Even with meters of the same design, differences among them which are not evident under normal conditions may become noticeable under abnormal conditions.

Discussion

The operation of a watt-hour meter depends upon the interaction of the fluxes produced by the component magnetomotive forces of the potential and current elements and the disk currents produced by the changing of those fluxes. The changes in these fluxes may be in either magnitude or position or both. The distribution of these fluxes in the meter and their variations in magnitude with time are important factors in the determination of the disk torque upon which the meter registration depends. Differences in both the space distribution of the fluxes with time for the various meters are determined to a large degree by the differences in the details in the designs of the meters. Although the details of element design have some influence, the time variation of the flux is determined largely by the external conditions in the circuit. The design of the magnetic circuit, with associated electrical circuits, practically determines the space distribution of the flux. Because of the variable timing of the magnetomotive forces of the potential and current elements the space distribution of their resultant flux is variable and hence is a function of external conditions as well as the magnetic design. In a like manner, the time variation of the resultant flux depends upon the variations in magnetic reluctance introduced by the magnetic design as well as the magnetomotive force variation dictated by external conditions. The materials of construction and their physical properties will have marked influences on the flux and hence on the characteristics of the meter.

It is the purpose, here, to discuss the effects of variations in the wave form of current and voltage, as fixed externally, on the registration of watt-hour meters.

Generally, the net conditions existing in and around any circuit where currents and voltage are nonsinusoidal can be considered to depend upon all components, fundamental and harmonics, present. This dependence may be difficult to determine unless linear relations exist. However, in most instances in power circuits, if harmonics are present to an important degree it is because of nonlinear response of iron in magnetic circuits to magnetization. In such cases the third and fifth harmonics are usually most prominent and except in instances of very high magnetic densities are the only ones of importance. Frequently only the third harmonic is sufficiently large to have much influence. For this reason, an experimental study of the effects of one major harmonic (the third) should give an understanding of the effects to be expected in practical cases.

In any case, net meter-disk torque should be produced only when voltage and current of the same frequency are used because in such cases only is there a net transfer of energy. This applies to harmonic components as well as to the fundamental. Experimentally it has been found that this is not true in all cases with practical meters. Net torque is produced even though voltages and currents of different frequencies are used. However, a distinction must be made between potentials and currents and the meter fluxes that result from them. The presence of iron in the magnetic circuits of the meters with its nonlinear response

to magnetizing forces will give rise to time variations in the fluxes of harmonics which are not present in the magnetizing forces. These harmonics may give rise to torque components which with reference to the torque produced by the fundamentals may be positive or negative. Figures 2–5 are reproductions of oscillograms showing the presence of such harmonics in the variation of the air-gap flux in a representative meter of recent design with only fundamental potential and current variations.

In certain single-phase watt-hour meters the cores of the current and potential elements are placed as shown in figure 1 relative to the disk. The points indicated along a center line of these cores designate positions at which the rates of variation of flux density are shown in figures 2, 3, 4, and 5. These rates of variation are for conditions specified and correspond to actual conditions of operation with sine waves of potential and current.

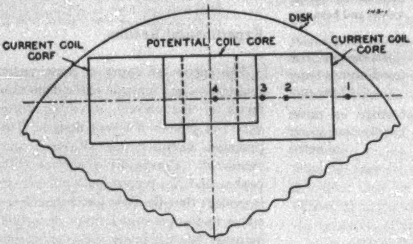

Figure 1. Plan—magnetic core of meter showing survey points

It will be noted that with sinusoidal potential impressed alone (figure 2), that the variations at all points approximate the sinusoidal. A careful analysis of these variations, however, shows that several harmonic components of small magnitude are present. The magnitudes at the various points differ widely. These conditions are to be expected since the flux linkages with the potential coil windings must vary in such a manner as to produce an induced voltage differing from the (sinusoidal) impressed voltage by only the resistance drop. This, with an iron core, requires that the induced voltage (and hence variation of flux) must contain harmonic components because of the harmonic content of the exciting current. These flux harmonics are of small magnitude relative to the fundamental as the curves of figure 2 indicate. The variations in amplitudes among the points are a result of the distribution of core material.

For the condition of the current coil alone, excited by sinusoidal currents (figure 3), the rates of variation of flux density at the various points are definitely nonsinusoidal. The nonlinear response of the iron to magnetizing force introduces harmonics of considerable magnitude. The influence of core distribution is evident.

With normal excitation for both potential and current elements, the resultant flux variation is not a superposition of those produced by each element acting independently. Portions of the magnetic circuit are influenced by both windings and having a nonlinear response, as stated before, will have resultant magnetic conditions which are not proportional to the component magnetizing forces. The conditions at the various points used to illustrate this are shown for two power factors in figures 4 and 5. In these cases the time relationship between the variations in flux density at the different points is not indicated in these figures.

Because of the difference in timing of the magnetomotive forces of the potential and current elements and the distribution of magnetic core material, the distribution of the resulting flux is not fixed. The variation includes both magnitude and position. Because of this shifting position and magnitude, a variable torque, tending to drive the disk, is produced. This variable torque can be considered as the resultant of many component torques, some positive, some negative. These components can be considered as produced by the fundamentals and harmonics in the space distribution and time variation of the air-gap flux as in any motor.

Although the net instantaneous torque in the case of sinusoidal potential and current is not uniform the single-phase watt-hour meter can be adjusted to give satisfactory registration characteristics. With external circuit conditions such that nonsinusoidal voltage or current or both exist, the proportions of the component

torques caused by harmonics will differ from that for which the meter is adjusted and the registration characteristics of the meter altered. The curves of figure 6 show the effects of nonsinusoidal waves of current.

In practical cases, either the voltage or current or both may be essentially sinusoidal functions of time, or either or both may differ sufficiently from the sinusoidal to warrant study. The probable combinations of conditions which may be encountered in practice are (1) both sinusoidal, (2) potential sinusoidal with current nonsinusoidal, (3) both nonsinusoidal. Since the effects of nonsinusoidal conditions are under consideration the base for comparison is taken as the combination (1) namely, the current and potential both sinusoidal.

For cases of nonsinusoidal conditions, varying degrees of distortion as well as various time relationships between harmonic components and the fundamental are considered. For purposes of establishing a measurable effect the distortion was limited to that caused by the presence of a third harmonic. Similar effects should be noted for other harmonics. It will be realized that as the number of harmonic components increases, the number of possible time relationships between the components increases beyond possible experimental study.

The term "distortion factor" is defined as "the ratio of the effective value of the residue after the elimination of the fundamental to the effective value of the original wave." (A.S.A. C-42-1932 section 10.95.430.)

For the case of nonsinusoidal variation of both potential and current an unlimited number of combinations are possible depending upon circuit conditions. Several examples are given, the conditions being noted with the curves showing experimental results.

Experimental Results

The curves of figure 6 show meter registration as a function of the distortion factor of the current wave for three makes of meters of recent design. The potential variation for all cases was sinusoidal. Curves are given for both peaked and flat-topped wave forms. It is evident that the disk speed should decrease as the per cent current distortion increases because under such conditions, the average power decreases. However, for all cases, the meter registration was computed as the ratio of actual disk speed to the disk speed for sinusoidal potential and current conditions giving the same average power. Although the large registration error, indicated on the curves, exists at large per cent values of current distortion, loads of this character are seldom experienced in practice.

For large values of distortion factor, the registrations of the meters with peaked currents differ greatly from those for flat-topped currents. These two wave forms can be considered as limiting cases of the time relationship between the fundamental and third harmonic components of current. For intermediate relationships of the components, intermediate values of the effects would be expected. Figure 7 shows the influence of the time relationship of the components for a constant-load and a constant-current distortion factor of 40 per cent.

Curves are shown for the three makes of meters as in figure 6. It can be noted that for all meters, flat-topped current waves gave the greatest meter registra-

tion with a sine wave of potential and that all meters showed about the same performance.

The performance of the meters differed widely for large values of current distortion factor, although all meters were adjusted to give correct registration with zero-distortion factor. Harmonic components in the currents in the current-element windings, through magnetic coupling between those windings and circuits in the details of design, give rise to harmonic currents in those circuits not in exact phase opposition to those in the current coils. These harmonic components may produce torques which have an appreciable magnitude relative to the fundamental torque. It was noted during the tests that 100 per cent current-distortion factor with the potential element unexcited some meters crept backward rapidly, some forward rapidly, and some did not creep. With the potential coil short-circuited or excited, disk movement was reduced in magnitude. At large values of distortion factor the summation of the torques due to harmonics became an important factor in the total torque.

All test meters responded similarly to variations in the phase angle between the fundamental components of potential and current. Figure 8 shows meter registration as a function of distortion factor for peaked waves of current and for three values of fundamental phase angle. The voltage and current were rated values.

For conditions of distortion in both potential and current waves, an unlimited number of combinations are possible. If the load is noninductive the distortion of both the waves should be the same. Under these conditions the time variations of the magnetomotive forces caused by both the potential and current circuits of the meter contain corresponding harmonic components. It should be noted, however, that the presence of corresponding harmonic components in the magnetomotive forces does not imply the presence of harmonic components in the fluxes having the same relative relationships as those of the magnetomotive forces.

Because of the higher frequency, the potential flux per volt for a harmonic is less than that for a fundamental. The variations in the air-gap flux will then be the resultant of components of different relative magnitudes than the respective component voltages. The effects of such conditions on the registration of a typical meter at various per cent loads and for peaked waves are shown in figure 9. Experimental results, using flat-topped waves, differed but slightly from those for peaked waves. In no case was this difference more than one-half per cent. With resistance loading, a reversal or change of any component in the voltage was accompanied by a corresponding change in the current component of that frequency. The net result of the change on the registration of the meters was of no practical magnitude. The flux density at which modern meter cores operate is low enough to make the effects of changing the maximum flux density (caused by change in wave form) small.

When the load circuit is inductive, the distortion factors of potential and current differ. One example of such loading gave results shown in figure 10. In this case, load resistance and inductance were of such values as to produce a fundamental phase displacement of approximately 37 degrees (0.8 power factor) the fundamental current lagging the voltage. Peaked waves of potential were used. The load power was constant.

Conclusions

1. Meter registration errors, as the result of wave distortion, for properly adjusted meters, usually will not exceed the limits of permissible calibration error unless the current-distortion factor is greater than 30 per cent.

2. Indicating instruments are recommended for use in the testing of watt-hour meters when the distortion factor of the current exceeds 50 per cent.

3. No definite statement can be made regarding the effects of distortion on meter registration if the potential distortion is the result of impedance drops caused by distorted currents since the time relationships of the harmonic components depend on circuit conditions.

4. Because of the differences in the space and time variations of the fluxes which would be produced by fundamental and harmonic components of potential, current or both, the net registration of a meter is not the summation of the registrations that the several harmonic components of potential and current would produce, each acting alone.

5. As a result of observations made during the tests it is believed that minor differences in the adjustments required to give satisfactory registration by meters of the same model may cause noticeable differences in the effect of wave distortion on the characteristics of the meters.

6. In the majority of meter applications where minor distortion of current or potential exists the watt-hour meter of recent design measures the energy satisfactorily if adjusted within the limits of commercial accuracy under customary testing conditions.

A New Principle of Cable Design

WM. A. DEL MAR
FELLOW AIEE

Synopsis: Study of cable behavior on load-cycle tests led to the conclusion that instability of the insulation results from its deformation, leaving ionizable voids in the inner layers, where deterioration starts.

This led to the conception of a cable in which the inner and outer layers of paper would have different moduli of elasticity, the outer papers having the higher modulus so that during the cooling period of a load cycle, the outer papers would compress the inner ones and so reduce or eliminate voids therein.

The tension of application of the tapes is the same for all layers and does not depart from ordinary practice.

It was found that cables made on this principle maintained a remarkable stability of power factor under load-cycle conditions.

Finally, a study of cable impregnants showed that an essential characteristic is stability under electrical discharges. An impregnant was developed consisting of a paraffin base oil with a definite proportion of a new synthetic derivative of wood rosin, which possesses this characteristic in a marked degree. This, used in combination with the above-described structure gives the maximum stability we have been able to attain.

IT HAS been the general belief that oil-filled paper cables differ from solid-type paper cables in that the former have a perfect radial and longitudinal flow and ebb of oil throughout the insulation during heat cycles whereas in the latter, the oil flows but does not ebb, perfectly, leaving ionizable voids in the depth of the insulation.

It is undoubtedly true that, in the oil-filled cable, the oil flow is reversible but our researches show that in the solid-type cable, there is little flow of oil out of the insulation at ordinary operating temperatures and, therefore, substantially no trouble to be expected from its imperfect ebb. The view is expressed herein that the real difference between an oil-filled cable and one of solid type is that, in the former, the oil is of such low viscosity that it can flow out and back again under pressure too small to deform the paper permanently, whereas in solid-type cables, the oil viscosity is so great that very high pressures are created by the expanding oil which tend to stretch the paper permanently, creating gaps between tapes which become vacuous when the oil contracts.

This is a useful conception of cable operation and a design of cable based upon it is described, the principle of which is to improve the effective elasticity of the mass of paper by using successive layers of increasing modulus of elasticity, so that each layer will be held in compression by circumjacent layers of greater modulus.

By this means the insulation of solid-type cable acquires some measure of the reversibility characteristic of oil-filled and pressure cables but without adding in any way to the dimensions or complications of the cable or its accessories.

The construction now used consists merely in the use of two layers of paper, the inner comprising three-fourths of the thickness, and the outer, one-fourth of the thickness of the insulation, the paper of the outer layer having a modulus of elasticity 15 per cent to 20 per cent greater than that of the inner layers.

Relative Imperviousness of Impregnated Paper to Viscous Oil Flow

Tests were made to establish the critical viscosity at which oil can move through insulation without exerting enough pressure to put undue stress on the paper.

Typical test results are shown in figure 1. It will be noted that with viscosities above 1,000 to 2,000 seconds there is but little pressure transmission through the insulation. Furthermore, in an operating cable, the oil temperature in the middle of the insulation will be considerably less than at the conductor, so that compound does not flow until the oil at the conductor surface has attained a considerably higher temperature than would be suggested by the data on figure 1.

Elastic Properties of Cable Paper

A study of the elastic properties of impregnated-paper cable was undertaken in order to better appreciate the stresses and strains arising from cyclical loading of cables. A cabinet was constructed capable of holding in vertical suspension a strip of paper one meter in length, changes in length being measured by means of a steel scale graduated in hundredths of an inch. Glued to the end of the paper was a piece of transparent celluloid which extended over the scale and upon which was scratched a hairline. The reading of the hairline was made to one-fourth of a hundredth-inch division through a glass door by means of an instrument-reading telescope. Humidity was regulated by means of anhydrous acids in a dish at the bottom of the tower. Tension was produced by means of a Chatillon spring scale. Humidity was measured by means of a calibrated Taylor humidiguide. The appearance of the setup is shown by figure 2.

It was found that impregnated-cable paper has peculiar physical properties, which would be likely to influence its behavior in a cable. The stress-strain characteristic of a typical cable paper is shown by figure 3. Different papers, however, have different slopes of curve, corresponding to different moduli. Although the graph is a straight line up to about 5,000 pounds per square inch, the paper is not perfectly elastic, within that range, but has a permanent set after each cycle of stretching, the amount of set rising with the tension. The relation between elongation and permanent set was found to be of the form shown by figure 4.

Armed with these data, the next step was to calculate the paper tensions that would result from oil expansion. This was started with the generally accepted idea that this expansion would cause the tape to stretch, thereby separating the layer sufficiently to permit the expanding oil to flow freely outward toward the sheath. The accepted idea was that in cooling, the elasticity of the paper would cause it to close in upon the contracting oil, even to the extent of the outer layers cutting off some of the oil before it could return to the interior of the cable.

It was found, on the contrary, that the paper did not stretch sufficiently to create the necessary oil passages between layers, but that, with the calculated stresses, the permanent set was sufficient to leave voids in cooling.

The obvious step to be taken to improve the quality of cable was to use a truly elastic paper, but we could not find a paper which showed true elasticity when impregnated. All papers tested showed more or less permanent set.

It was noted, however, that different papers had different moduli of elasticity and the idea presented itself of placing layers of paper of high modulus over layers of low modulus so that as the inner papers were stretched by the expanding

Paper 41-71, recommended by the AIEE committee on power transmission and distribution, and presented at the AIEE winter convention, Philadelphia, Pa., January 27-31, 1941. Manuscript submitted November 16, 1940; made available for preprinting December 16, 1940.

Wm. A. Del Mar is chief engineer for the Habirshaw Cable and Wire Division of the Phelps Dodge Copper Products Corporation, Yonkers, N. Y.

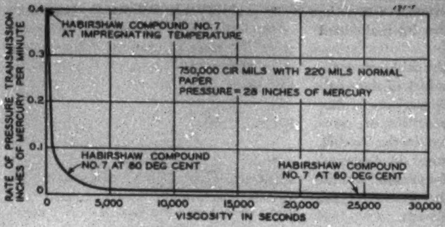

Figure 1. Relative imperviousness of impregnated-paper cable to viscous oil under pressure

Viscosities above 3,500 seconds which could not be measured on the Saybolt universal viscosimeter were measured by rate of penetration through single sheets calibrating the sheets with an oil of known viscosity

oil, they would meet resistance by the outer layers and in cooling, the pressure exerted by these outer layers would help to restore the inner layers to their original condition.

In order to test the correctness of this theory, cables were made with two grades of paper, the inner layers being made with the normal paper and the outer layers with paper having about 20 per cent greater modulus of elasticity. These cables were tested in comparison with cables of normal construction by means of load-cycle life tests.

Accelerated Aging Tests

The best available data on the correlation of accelerated aging with natural aging were those of the Commonwealth Edison Company published by D. W. Roper, AIEE TRANSACTIONS, volume 52, 1933, page 1028 and by Halperin and Betzer, AIEE TRANSACTIONS, volume 55, 1936, page 1074.

In order to ensure that our tests should be equally correlated with service conditions we decided to make our tests at the same maximum stress, as in the Halperin-Betzer tests, namely 208 volts per mil and at a conductor temperature five degrees centigrade over the normal operating temperature. When meter corrections were taken into account, our actual maximum stress was 203 volts per mil. The cable type selected for test was a 4/0 AWG, 19 strand, single-conductor cable with 220 mils of insulation and 63 mils lead sheath.

Heating current was maintained for eight hours per day, five days per week. Voltage was maintained the full 24 hours and over weekends, except for intervals while measurements were being made.

Figure 2. Test chamber for modulus determination

Roper reported that tests made under these conditions gave failure of similar nature to those occurring in service and that it would be unnecessary to carry the tests to failure as the rising power factor, ionization and hot-spot temperature would differentiate between cables of different qualities in the course of from two to seven weeks, i.e., 10 to 35 load cycles.

Our preliminary work showed that this generalization was also applicable to our tests.

> Poorly impregnated cables, i.e., cables drained of part of their oil, were eliminated in two weeks, i.e., 10 or 12 load cycles.
>
> Questionable cables were eliminated in four weeks, i.e., 20 load cycles.
>
> Good cables, as then made, lasted at least five or six weeks, i.e., 25 to 30 load cycles.

Roper found that whereas tests made at $2^1/_2$ times operating voltage, corresponding to a maximum stress of 208 volts per mil were indicative of service life, those made at three times operating voltage, corresponding to a maximum stress of 250 volts per mil, had no such significance but, on the contrary, were quite erratic.

The suggestion that tests be discontinued before failure, was a fruitful one as it not only enabled more tests to be made in a given time, but also permitted examination of the cable where failure seemed imminent and before destruction of the evidence occurred. The tapes from a typical arrested failure on a cable of ordinary type is shown in figure 5.

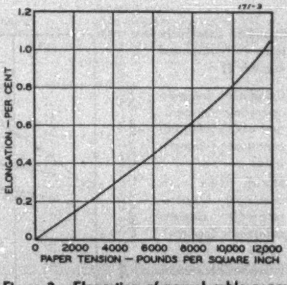

Figure 3. Elongation of normal cable paper impregnated

As the tests were to be discontinued when the cables showed signs of instability, it was necessary to establish arbitrary limits indicative of this condition.

The Commonwealth Edison limits and those we adopted were as follows:

	Commonwealth Edison Company	Habirshaw
Power factor at 85 degrees centigrade		2.00
Rise of power factor at high temperature of cycle (per cent)	0.75	
Rise of ionization (per cent)	0.50	0.50
Hot-spot temperature rise (degrees centigrade)	8	8

Each test was made on a set of four cables impregnated at the same time, each 15 feet long and equipped with pressure-tight terminals. The initial power factors on these four supposedly identical cables were nearly equal but not identical. As, however, they tended to equalize after a few load cycles, it seemed fairer to set the limit at a certain final power factor rather than a definite rise from the start. A value of two per cent was chosen as giving results close to those of the Commonwealth Edison Company.

The first load-cycle tests were made with two sets of cables, one made up with 160 mils of normal or type *N* paper surrounded by 60 mils of high modulus or type *S* paper, a construction referred to for convenience as "Titebilt," the other

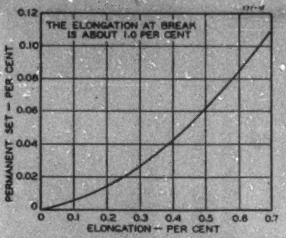

Figure 4. Permanent set of normal cable paper impregnated

made with the same total thickness of paper as ordinarily used, i.e., 50 mils of paper, selected for high density, covered with 170 mils of type *N* paper. The average number of cycles required to reach the limits set were as follows:

Set Number 1

Construction	Power Factor	Ionization	Hot Spot	Breakdown
Ordinary	25	25	22	25
Titebilt	60	82	64	82

Another series of tests was made, adding, however, a set of cables made entirely of type *S* paper. It was expected that if the elasticity theory were correct, the cables made of this kind of paper should be inferior to the Titebilt cable. This was confirmed by the following results:

Construction	Average Number of Load Cycles to Reach Power-Factor Limit Set Number 2
Ordinary construction	30
220 mils of type *S* paper	42
Titebilt	69

The progress of power-factor rise in the Titebilt and ordinary cables for set number 2 is shown in figure 6. It will be noted, that the Titebilt cable shows a smoothly rising curve which contrasts remarkably with the erratic curve of the ordinary cable. The power-factor curve of the Titebilt cable did not show any final upturn until two or three cycles before failure.

The above tests were confirmed by two more sets of tests as follows:

	Load Cycles to Reach Power-Factor Limit	
Construction	Set Number 3	Set Number 4
Ordinary	27	29
Titebilt	72	75+

Set number 4 was stopped when the Titebilt cable had shown its undoubted superiority.

After all these tests the cables were examined and a large amount of data collected. After the stability of power factor, the first feature noted was the complete absence of dendrites in the Titebilt cables. Cable wax formed in cables of both types, but less frequently and in smaller amounts in the Titebilt type. The exact data are as follows:

Construction	Cables With Dendrites (Per Cent)	Cables With Wax (Per Cent)
Ordinary	36	57
Titebilt	0	25

No gas was found in the tape-edge channels of the Titebilt cables whereas many of the other cables showed varying amounts of gas.

The average ionization of cables of the ordinary type was 0.069 per cent at the end of the life tests whereas that of Titebilt cables was 0.058 per cent in spite of the fact that the latter lasted more than twice as many cycles on life test.

Four lengths of Titebilt cable constituting set number 5 were tested on load cycle at 243 volts per mil, maximum stress which, as indicated above, is too high to yield results comparable with operating conditions. Two of these developed slight dendrites in the *outer* half of the insulation. The dendrites in ordinary cable always appeared in the inner half of the insulation. This shows that the inner part of the insulation, which carries the highest electrical stress at operating voltages, remains tighter in the Titebilt cable, affording an interesting proof of the Titebilt principle. The same peculiarity has since been noted in Titebilt cables tested to breakdown in accordance with AEIC specifications.

In addition to these five recorded sets of tests, there were numerous preliminary tests and tests to obtain specific design data, all of which substantiated the Titebilt design.

Belted Cable

So far, all the discussion has related to single-conductor cable, although obviously, the Titebilt idea is equally applicable to multiple-conductor shielded cable. The principle is not so easily applied to the belted cables, but considerable benefit has been found to result

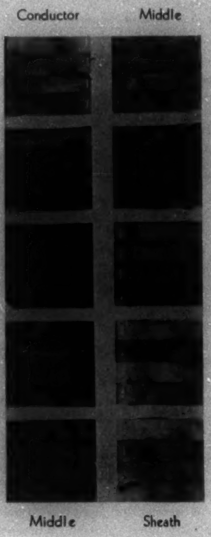

Figure 5. Arrested failure of ordinary cable

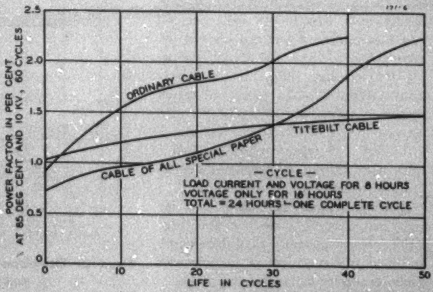

Figure 6. Life-cycle tests (compound number 7)

Conductor maximum operating temperature = 85 degrees centigrade (approximate)

Sheath maximum operating temperature = 60 degrees centigrade (approximate)

Room temperature = 25 degrees centigrade (approximate)

Figure 7. Three-phase load-cycle test equipment

from using the Titebilt composite construction for the conductor insulation.

For instance, one such test was on cable having an AEIC rating of 12,000 volts. It was tested at 24,000 volts; i.e., at twice rated voltage, but the copper temperature was brought up to 85 degrees centigrade. After 30 cycles the Titebilt cable power factor at 85 degrees centigrade rose from 1.01 to 1.06 per cent, whereas that of the old type cable rose from 1.04 to 1.22 per cent. The layout for this test is shown in figure 7.

In general, these tests showed that Titebilt belted cable was consistently superior to the old type cable but by a smaller margin than in the case of the single-conductor and shielded cables.

Compound Number 8

The tests recorded above were all made with compound number 7, a preponderantly paraffin base oil with 15 per cent wood rosin. The following tests were made with cables of the Titebilt construction, using compound number 8 consisting of the same oil with ten per cent of a synthetic derivative of rosin, namely hydrogenated wood rosin.

The type of test on single-conductor cables, described above, proved to be quite inadequate for cables made in this way. It will be remembered that while ordinary cables attained the two per cent power factor (85 degrees centigrade) limit in from 25 to 30 load cycles and the original Titebilt cables in from 60 to 75 load cycles, there was no indication that Titebilt cable with compound number 8 would attain the limit within two or three times that number. In fact, the test seemed to have no effect on the power factor of the cable.

The compound itself, tested, in a new type of bombardment cell, shown in figure 8, gave remarkable results. In preparing a sample of oil for test, the assembled discharge cell is placed on a water bath held at 100 degrees centigrade, and is then evacuated to an absolute mercury pressure of 0.1 millimeter, the residual being air. A sample of oil weighing 25 grams is poured into the funnel of the oil inlet, from which it is slowly drawn into the discharge chamber and degassed. After degassing the apparatus is allowed to stand for one hour at room temperature. At this time, a potential of 9,000 volts, 60 cycles, is applied to the test cell from a gas-sign transformer, and continued for 1,000 minutes. The relative oil stabilities are determined by change of power factor as measured in a Davidson power-factor cell. Whereas in this cell compound number 7 ended the test with a power factor of 4.0 per cent at 85 degrees centigrade, compound number 8 underwent the same ordeal and ended with a power factor of 0.4 per cent. This compound mixes with joint oils, in all proportions, without appreciable rise of power factor.

Table I. Load-Cycle Test of Titebilt Cable

Three-Conductor, 500,000-Circular-Mil, Type *H*, 122 Mils of Insulation (Rated at 7,000 Volts), 117 Mils of Lead

	Load Cycles		Hours			
Week*	Number of Cycles	Maximum Temperature (Degrees Centigrade)	Heating	Cooling	Power Factor at 60 Degrees Centigrade (Per Cent)	Ionization Per Cent at Room Temperature

*Saturdays and Sundays, after each week of test, the cables carried 24 kv but no load current.

Ionizations which were reported as having small negative values are entered as zero.

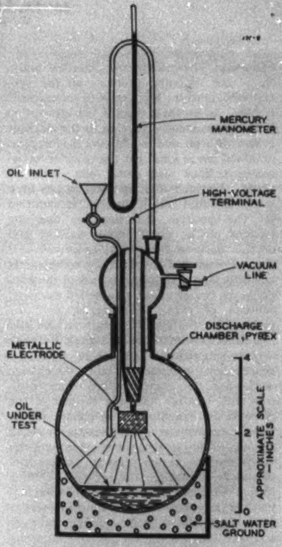

Figure 8. Merrell discharge cell for oil-stability tests

At this stage of our work Mr. Halperin called our attention to a new type of load-cycle test which he had developed that was calculated to be more destructive than the old and we decided to test a three-conductor shielded cable of the new design. This test procedure is described in his 1939 AIEE paper. Like the earlier one, it uses heating and cooling periods with voltage but instead of a single upper temperature of 85 degrees centigrade, it includes cycles at conductor temperatures of 60, 80, 100, and 115 degrees centigrade at twice operating voltage, corresponding to an average stress of 114 volts per mil and a maximum stress estimated at about 195 volts per mil, i.e., substantially the same as in the earlier tests.

The main criteria of stability are the change in the ionization factor at room temperature and in the power factor at 24 kv and 60 degrees centigrade, so that a cycle at that temperature was made after each of the groups of cycles at higher temperatures.

Positive and Negative Damping in Synchronous Machines

M. M. LIWSCHITZ
MEMBER AIEE

Synopsis: The straight mathematical analysis of the damping problem on the synchronous machine leads to very complicated results. From these results, the conception of the phenomena occurring in the machine is very difficult and in addition the formulas obtained are so long that the calculation becomes tedious and errors can easily be made. In this paper, an attempt has been made to find a simple physical explanation for the positive and negative damping torques of the synchronous machine and on this basis to derive simpler formulas for the calculation of the damping torques. It has been found that the torque of the synchronous machine, as a double-fed machine, consists of three components, two dependent on the speed of the machine and the third dependent on the angle between the rotating field and the rotor. When the synchronous machine oscillates, the change of the first two components produces positive and negative damping torques of the synchronous machine. The change of the third component produces the synchronizing torque. The positive damping torque depends mainly on the primary voltage and secondary resistance; the negative damping torque depends mainly on the excitation and the primary resistance. This knowledge made it possible to derive a simple and very accurate formula for the positive damping torque as well as a simple approximate formula for negative damping torque. On the basis of these formulas, the influence of the two axes of the machine on the damping can be easily found. A comparison between the results obtained by using the simple formulas and the long accurate formulas as well as a comparison between calculation and test on a small machine have been carried through.

I. Simple Equations for Determining the Damping and Synchronizing Torque

FOR the purpose mentioned, a symmetrical machine will be considered first, both parts of which have polyphase windings carrying currents of different frequencies f_1 and f_2. The frequency f_1 as well as the corresponding voltage E_{L1} are assumed to be constant. All quantities and constants involved will be reduced to terms of this side of the machine. As shown in appendix the torque of such a machine is equal to (all values in per unit notation)

$$T=[e_1{}^2sr_2-e_2{}^2r_1+e_1e_2\sqrt{l_1{}^2+m_1{}^2}\times \sin(\delta_0+\alpha)]\frac{1}{l^2+m^2} \qquad (1)$$

l_1, m_1, l, and m are functions of the slip $s=f_2/f_1$.

Thus the torque consists of three components. The first two components are dependent on the speed of the machine, the third component is dependent on the speed of the machine as well as on the angle between the both line voltages e_1 and e_2. The first component is the well-known torque of the normal induction machine.

The synchronous machine is a special case of the double-fed machine, with $f_2=0$ and $e_2=I_2r_2$.

The three components of the torque T (equation 1) will change their value when the double-fed machine oscillates. To the change of the first two components will correspond a damping torque, to the change of the third component will correspond a synchronizing torque.

Thus the damping torque consists of two components, one positive and the other negative. The positive component is proportional to the square of the primary voltage and is dependent on the secondary resistance; it is equal to zero, when the secondary resistance is equal to zero. The negative component is proportional to the square of the secondary

Paper 41-56, recommended by the AIEE committee on electrical machinery, and presented at the AIEE winter convention, Philadelphia, Pa., January 27–31, 1941. Manuscript submitted October 23, 1940; made available for preprinting December 13, 1940.

M. M. LIWSCHITZ is consulting design engineer for the Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.

[1] For all numbered references, see list at end of paper.

A test of this kind on Titebilt cable with compound number 8 is described below.

Shielded Three-Conductor Cable

A cable of the following construction was made, having an AEIC rating of 7,000 volts and tested at 24,000 volts in accordance with procedure described above.

Three-conductor 500,000 circular mils
Insulation 122 mils $\begin{cases}\text{type } N\text{, 90 mils}\\ \text{type } S\text{, 30 mils}\end{cases}$
Impregnant, compound number 8
Shield, three-mil copper with intercalated paper
Fillers, paper
Binder, five-mil bronze
Lead, copper bearing, 117 mils
Length of test piece, 25 feet under lead
Position of ends during test, horizontal
Condition during test, pressure tight

The cycles of load are given in table I with the power factors at 60 degrees centigrade at the end of each week. It will be noted that the new Titebilt cable, showed substantially no change in either power factor or ionization. Two cables were subjected to the above test and a third one to the first four weeks only, with the same result. A 115-foot sample of the same cable was subjected, at Chicago, to the same type of test with practically the same results.

Similar tests are recorded by Halperin, AIEE TRANSACTIONS, volume 58, 1939, page 536, where it is shown that standard 12,000-volt ($^9/_{64}$ inch by $^5/_{64}$ inch) belted cables made in 1937 and 1938 show power-factor increases of 19 to 300 per cent of the original values and ionization rises from substantially zero to 0.5 per cent, absolute values.

While Titebilt cable was developed along the line of scientific utilization of mechanical properties of paper, the disposition of the papers planned on that basis may, and probably does, lead to a better arrangement from other points of view, which I hope to express on some subsequent occasion.

voltage and is dependent on the primary resistance; it is equal to zero, when the primary resistance is equal to zero or when the secondary voltage (in terms of the synchronous machine, the excitation) is equal to zero. The positive component of the damping torque will be called rotor-damping while the negative component will be called stator-damping.

It is now possible to derive a simple formula for the rotor-damping of the synchronous machine (1 and 3). It is (for the symbol s. List of Symbols)

$$T_{\text{rot.}}=\frac{e^2}{Z}\left[\frac{r_{2d}/s_p}{Z_{sd}^2}\sin^2\delta_0+\frac{r_{Dq}/s_p}{Z_{sq}^2}\cos^2\delta_0\right] \quad (2)$$

where

$$s_p=\frac{Z}{\omega}\quad \tau_{1d}=\frac{x_1}{x_{ad}}\quad \tau_{1q}=\frac{x_1}{x_{aq}} \quad (3)$$

$$x_{sd}=x_1+(1+\tau_{1d})x_{2d}\quad x_{sq}=x_1+(1+\tau_{1q})x_{Dq} \quad (4)$$

$$Z_{sd}^2=[(1+\tau_{1d})r_{2d}/s_p]^2+x_{sd}^2$$
$$Z_{sq}^2=[(1+\tau_{1q})r_{Dq}/s_p]^2+x_{sq}^2 \quad (5)$$

The rotor damping of the asynchronous machine is determined directly by the slope of the speed-torque curve which is represented by the first component of the equation 1. The rotor damping of the synchronous machine is dependent on this slope at $s=0$ and in addition is modified by the angle δ_0 which determines the power of the synchronous machine.

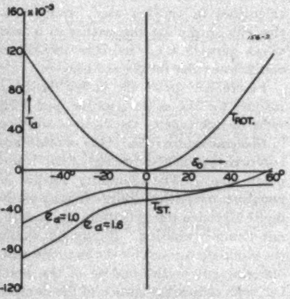

Figure 2. Direct axis

The result given by the equation 2 will be compared with that obtained by Doherty and Nickle in their "Synchronous Machines, Part III"[2] where r_1 is assumed to be equal to zero. The comparison will be made for a 48-pole machine of 2,500 kva, 6,000 volts, 50 cycles, but in order to make the negative damping more noticeable, it will be assumed that this machine has an abnormally high stator resistance, and that it operates on 1,000 volts, 8 cycles per second. Under these conditions, the constants are:

$r_1=0.20$ $\quad r_{2d}=0.022$
$x_1=0.116$ $\quad x_{2d}=0.301$
$x_{ad}=0.855$ $\quad r_{Dq}=0.078$
$x_{aq}=0.519$ $\quad x_{Dq}=0.08$

Further, it is assumed that $Z=5.03$; i.e., $s_p=0.10$.

The curve $T_{\text{rot.}}$ in the upper part of figure 1 was calculated by using the formula contained in said paper, the circles were calculated by using equation 2. The agreement is very satisfactory, as has been found on many other occasions.

Unfortunately, it is not possible to find a similarly simple and accurate formula for the stator (negative) damping. On the basis of the second term of the equation 1 and with support of calculations using the exact formulas it is possible, however, to derive an approximate formula that gives satisfactory results for the usual range of δ_0($\delta_0=+35$ degrees to -35 degrees) and for excitations corresponding to $e_d=1.0$ to 1.6.

When using the second term of the equation 1 it has to be considered that in the synchronous machine the voltage e_2 corresponds to the ohmic drop of the secondary current and that this current multiplied by the reactance of the armature reaction is equal to the electromotive force induced in the stator. Thus the main quantities of the second term of the equation 1 are involved. The influence of the angle δ_0 upon the stator damping is taken into account by two factors k_1 and k_2 based on the exact formulas. Thus, the approximate formula for the stator-damping is:

$$T_{\text{st.}}=-\frac{e_2}{Z}\frac{r_1}{\left(\frac{x_{ad}+x_{aq}}{2}\right)^2}\times$$
$$\left[\left(\frac{e_d}{e}\right)^2\frac{(r_{2d}/s_p)^2}{Z_{sd}^2}k_1+\frac{(r_{Dq}/s_p)^2}{Z_{sq}^2}k_2\right] \quad (6)$$

For a generator:

$k_1=1-\tan^2\delta_0 \qquad k_2=1-\sin 2\delta_0$

and for a motor:

$k_1=1+\tan^2\delta_0 \qquad k_2=1-\sin\dfrac{\delta_0}{2}$

The values of the resultant damping torque $T_{d\,\text{res.}}=T_{\text{rot.}}+T_{\text{st.}}$ given by the equations 2 and 6 will be compared with those obtained by Park[4] on the assumption $x_{ad}=x_{fd}$ and $x_{aDq}=x_{aq}$. As in the comparison with Doherty and Nickle, it is further assumed that there is only one winding in the direct axis.

In the figure 1 the curves $T_{\text{res.}}$ are the torques obtained by using Park, the crosses and circles are values calculated from the equations 2 and 6. The agreement is satisfactory. It should be remarked that the damping torques obtained by Nickle and Pierce[5] for the running as a *motor* at the heavier loads are about 30 per cent higher than those obtained by Park; i.e., in this range the method of Nickle and Pierce gives too small values for the negative damping.

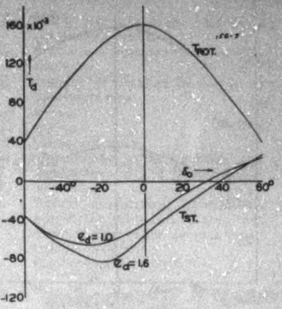

Figure 3. Quadrature axis

In the bottom part of the figure 1 is shown separately the stator (negative) damping torque. The negative damping is much larger when the machine operates as a motor than when it operates as a generator. For the same (absolute) value of the angle δ_0 the resultant damping for the motor is much lower than for the generator. The negative damping torque increases with increasing excitation. This influence of the excitation is also larger for the motor than for the generator The rotor-damping of the synchronous machine is positive for any angle δ_0, while in the normal induction machine the rotor-damping can also be negative. In the normal range of δ_0 the stator-damping of the synchronous machine is always negative, however, at large *positive* values of δ_0 it can become positive.

The figures 2 and 3 show the rotor-damping as well as the stator-damping for both axes separately. For small values of δ_0 the negative-damping in the direct axis is greater than the positive damping, while in the quadrature axis the negative damping is at any angle δ_0 smaller than the positive damping.

The curve T_d of the figure 4 gives the comparison between the results obtained by Park and those obtained by using the equations 2 and 6 for the same machine as above, but at 50 cycles, $s_p=0.027$ and a primary resistance 70 per cent higher than normal. The agreement between both methods of calculation is satisfac-

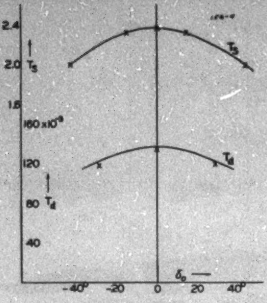

Figure 4

tory. The shape of this curve T_d is typical for the standard larger generators having a low-resistance damper winding. Here the influence of the negative damping is small, and the damping torque can be calculated by using equation 2 only.

The mathematical analysis used in deriving an expression for the damping torque also leads to the synchronizing torque. Since the equations for the synchronizing torque derived in the papers mentioned above (2, 4, and 5) are very complicated, a simple equation for the synchronizing torque was derived that corresponds to equation 2.[11] This equation is

$$T_s=\frac{ee_d}{x_d}\cos\delta_0+e^2\frac{x_d-x_q}{x_dx_q}\cos 2\delta_0+ e^2\left[\frac{x_{td}}{(1+\tau_{1d})Z_{sd}^2}\sin^2\delta_0+ \frac{x_{tq}}{(1+\tau_{1q})Z_{sq}^2}\cos^2\delta_0\right] \quad (7)$$

The results given by this equation will be compared with those obtained by Doherty and Nickle.[3] The curve T_s in figure 4 shows the comparison for $e_d=1.6$. The agreement is very good, as has been found on other occasions. The correctness of equation 7 is proved by the results of experimental determinations of the natural frequency.

II. Tests to Determine the Damping Torque

There are very few tests published for determining the damping torque of a synchronous machine while the machine is hunting. Some valuable data are given by F. A. Hamilton.[10] Systematic tests, suggested by the author of this paper, were made by R. Kuenmich at the University of Stuttgart.[9] A small 4-pole, 1.6-kva, 50-cycle synchronous machine having an external field system was used in making these tests. The primary resistance was equal to 0.072; the material of the damper winding was copper. The damping torques are given in figure 5*B* for the machine without damper winding and in figure 5*A* for the machine with damper winding. Both diagrams reveal that the damping torque increases with increasing load and that it decreases with increasing excitation. It could not be expected, however, that this influence of the excitation would be appreciable in the large machines used by Hamilton in making his tests.

It follows from figure 5*B* that for the point $P=0.2$ kw and $i_f=1.66$ amperes, the torque $T_d=-14.1\times10^{-3}$. By using Park, the calculated torque under these conditions is found to be $T_d=-12.1\times10^{-3}$; by using the equations 2 and 6, it is found to be $T_d=-12.4\times10^{-3}$. The agreement is satisfactory, if it is considered that the accuracy of the tests is from ±10 to ±20 per cent. Figure 5*A* gives for the point $P=1.6$ kw and $i_f=1.66$ amperes, the torque $T_d=9.3\times10^{-3}$. By using Park the calculated torque is found to be $T_d=23.7\times10^{-3}$; by using the equations 2 and 6, it is found to be $T_d=20.6\times10^{-3}$. The calculation does not check with the test. This is only partly a result of the limited accuracy of the tests. The main reason for the discrepancy is the difficulty of properly determining the constants of the machine, especially in the present case, where the saturation is high (the ratio of no-load AT to gap AT being equal 1.57). In addition, the frequency of the oscillations is high and therefore the assumptions for the derivation of the formulas are not fully justified. The papers of Linville[7] and Waring and Crary[8] were used in calculating the constants. Only the constants of the damper winding were calculated in another way; namely, in the way shown by the author in a previous paper[12] (i.e., by introducing an equivalent value for the *y* of Linville).

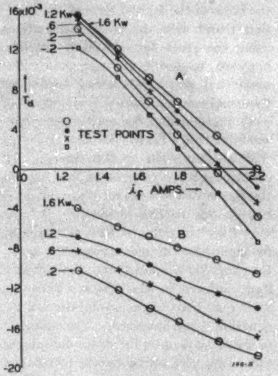

Figure 5

A—Damping torque with damper winding

B—Damping torque without damper winding

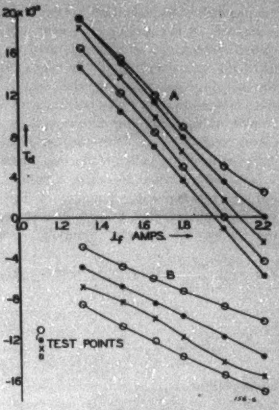

Figure 6

A—One ring open in the middle of the pole

B—One ring open in the middle of the interpolar space

Figure 6*A* shows the tested damping torques for the same machine, but with reduced influence of the damper winding in the quadrature axis. One of the rings has been cut in the middle of the interpolar space. The damping torque is negative over the entire range, as in figure 5*B* which refers to the machine without damper winding. Figure 6*B* shows the damping torques for the machine with one ring cut in the middle of the pole; i.e., with reduced influence of the damper winding in the direct axis. It is worth noticing that the torques are now larger than in figure 5*A* which refers to the machine with normal squirrel-cage damping. The reason for this can be seen from figure 2. The tested machine has a small angle δ_0 ($\delta_0=11.5°$ at 1.6 kw) and a small angle δ_0 may cause the negative damping in the direct axis to be stronger than the positive damping. In some cases (for example, when the machine is used for electric ship propulsion) it may be useful to cut the ring in the middle of the pole for this would reduce

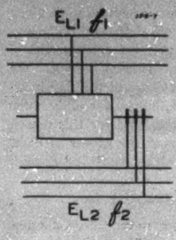

Figure 7

the short-circuit current without appreciably changing the damping torque.

Appendix

For the machine as per figure 7, it will be assumed that the stator voltage E_{L1} and the stator frequency f_1 are constant. All values will be reduced to terms of the stator. If the rotor rotates in the direction of the field produced by the stator currents:

$$n=\frac{120(f_1-f_2)}{p}=\frac{120f_1(1-s)}{p} \qquad s=\frac{f_2}{f_1} \tag{1}$$

Assuming that the iron losses are negligible and that the vectors E_{L1} and E_{L2} are displaced by an angle δ, it is found that

$$\mathbf{Z}_1=r_1+jx_1 \qquad \mathbf{Z}_2=r_2+jsx_2 \tag{2}$$

$$E_{L1}=-\mathbf{E}_1+\mathbf{I}_1\mathbf{Z}_1 \quad E_{L2}e^{-j\delta}=-s\mathbf{E}_1+\mathbf{I}_2\mathbf{Z}_2 \tag{3}$$

$$\mathbf{I}_m=\mathbf{I}_1+\mathbf{I}_2=j\mathbf{E}_1\frac{1}{x_m} \tag{4}$$

The author has shown in a previous paper[13] that it is useful to apply the "superposition principle" in treating the double-fed machine. With this principle, the stator current will consist of two parts, one produced by the stator voltage on the assumption that the rotor is short-circuited, the other produced by the rotor voltage on the assumption that the stator is short-circuited. The same is valid with reference to the rotor current. Thus

$$\mathbf{I}_1=\mathbf{I}_{11}+\mathbf{I}_{12} \qquad \mathbf{I}_2=\mathbf{I}_{21}+\mathbf{I}_{22} \tag{5}$$

From the equations 2 to 5 follow the four current components:

Stator:

$$\mathbf{I}_{11}=E_{L1}\frac{f+jk}{l+jm}$$

$$\mathbf{I}_{12}=-E_{L2}\frac{\cos\delta-j\sin\delta}{l+jm} \tag{6}$$

Rotor:

$$\mathbf{I}_{21}=-E_{L1}\frac{s}{l+jm}$$

$$\mathbf{I}_{22}=E_{L2}\frac{(\cos\delta-j\sin\delta)\left(1+\tau_1-j\dfrac{r_1}{x_m}\right)}{l+jm} \tag{7}$$

where

$$\tau_1=\frac{x_1}{x_m},\ \tau_2=\frac{x_2}{x_m},\ f=(1+\tau_2),\ \ k=-\frac{r_2}{s}\frac{1}{x_m} \tag{8}$$

$$l=\left[(1+\tau_2)r_1+(1+\tau_1)\frac{r_2}{s}\right]\times s$$

$$m=\left[x_1+(1+\tau_1)x_2-\frac{r_2}{s}\frac{r_1}{x_m}\right]\times s \tag{9}$$

The torque is given by the equation

$$T=E_{L1}\bullet\mathbf{I}_1-\mathbf{I}_1^2r_1=j\mathbf{I}_1\bullet\mathbf{I}_2x_m \tag{10}$$

The dot (•) indicates that the scalar product of the two vectors has to be taken. Thus

$$T=j\mathbf{I}_{11}\bullet\mathbf{I}_{21}x_m+j\mathbf{I}_{11}\bullet\mathbf{I}_{22}x_m+j\mathbf{I}_{12}\bullet\mathbf{I}_{21}x_m+ \\ j\mathbf{I}_{12}\bullet\mathbf{I}_{22}x_m \tag{11}$$

By evaluating these four scalar products and using the abbreviations

$$l_1=\left[(1+\tau_2)r_1-(1+\tau_1)\frac{r_2}{s}\right]\times s$$

$$m_1=x_1+(1+\tau_1)x_2+\frac{r_2}{s}\frac{r_1}{x_m} \tag{12}$$

$$\tan\alpha=\frac{l_1}{m_1} \tag{13}$$

the equation 1 will be obtained.

List of Symbols

e_1, e_2	terminal voltage
E_L	line voltage
E_I	induced electromotive force
f_1, f_2	line frequency
f_p	frequency of the oscillation
I	current
I_m	magnetizing current

Control of the Switching Surge Voltages Produced by the Current-Limiting Power Fuse

E. A. WILLIAMS, JR.
ASSOCIATE AIEE

C. L. SCHUCK
ASSOCIATE AIEE

Synopsis: A new transient condition unique to fuses of the current-limiting type is described and it is recommended that these fuses be designed to inherently control switching surge voltage magnitudes to meet the following conditions:

1. The transient recovery voltage should not exceed the insulation level of rotating machines $\sqrt{2}(2E+1{,}000)$ where E is the rated terminal-to-terminal rms voltage of the lowest rated machine involved.

2. The transient recovery voltage should preferably not exceed the 60-cycle crest spark-over voltage of associated lightning arresters.

3. If the transient recovery voltage does exceed the 60-cycle crest spark-over voltage of associated arresters, the interrupting rating of the fuse should be determined and assigned to limit the arrester current to a safe magnitude.

These conditions may be met by current-limiting fuses employing conducting elements having two or more sections of different diameters. Such fuses have been designed and are now commercially available. Typical oscillograms illustrating the operation of these fuses are included.

Introduction

It is generally recognized that most circuit-interrupting devices may be expected to produce a transient switching surge voltage having a magnitude appreciably in excess of the normal crest voltage. The magnitude of this transient voltage is a function of the characteristics of both the interrupting device and the circuit interrupted. To this background of existing and recognized transient voltage conditions may be added a relatively new phenomenon; the switching surge voltage (transient recovery voltage) of the current-limiting fuse.[1,2] This type of fuse tends to interrupt short-circuit currents so quickly that unless the interruption is properly controlled, the transient recovery voltage may reach a very high magnitude. With proper control, the transient voltage can be held within allowable safe limits.

The switching surge voltage of a current-limiting fuse differs from that of other interrupting devices in that the energy associated with the surge may be considerably greater. This difference results from the fact that the fuse limits the current by rapidly inserting arc resistance into the circuit at the instant the current-responsive element volatilizes. Since the high-resistance steady-state arc voltage of the fuse is practically equal to open-circuit voltage, the "recovery" occurs at the inception of the arc and *before* the interruption of the short-circuit current. With other interrupting devices, the voltage recovers at the end of the arcing period and *after* the interruption of the short-circuit current. Thus, the switching surge voltage of the fuse is associated with a definite value of dynamic short-circuit current and for this reason a new conception of the effects of transient recovery voltage must be considered.

The purpose of this paper is:

1. To call attention to the nature of a new switching transient phenomenon.
2. To point out the desirability of controlling the new switching transient to prevent damage to associated equipment.
3. To describe a method of designing current-limiting fuses with effective means of controlling switching surge voltages.

Permissible Limits for Switching Surge Voltages

Permissible limits for switching surge voltages should be based on several factors, one of which is the insulation level of rotating machines. Transformers and similar apparatus are considered to have an impulse ratio in the order of two or more, whereas rotating machines should be considered to have an impulse ratio only slightly greater than unity.[3] For

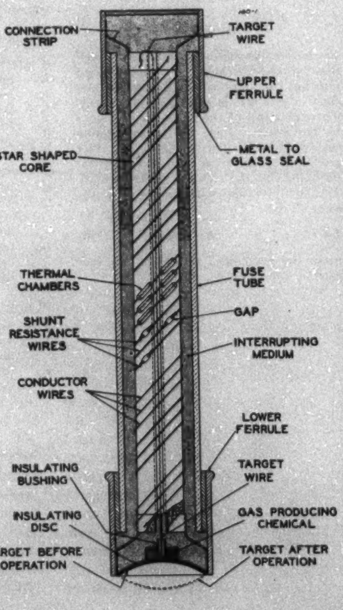

Figure 1. Current-limiting fuse with shunt-resistance wires

Paper 41-60, recommended by the AIEE committee on protective devices, and presented at the AIEE winter convention, Philadelphia, Pa., January 27–31, 1941. Manuscript submitted November 28, 1940; made available for preprinting December 13, 1940.

E. A. Williams, Jr., and C. L. Schuck are in the switchgear engineering department of the General Electric Company, Philadelphia, Pa.

The authors wish to acknowledge the parallel work of several European companies along the lines described in this paper. The contribution of K. A. Lohausen, Allgemeine Elektricitäts-Gesellschaft, is particularly noteworthy.

[1] For all numbered references, see list at end of paper.

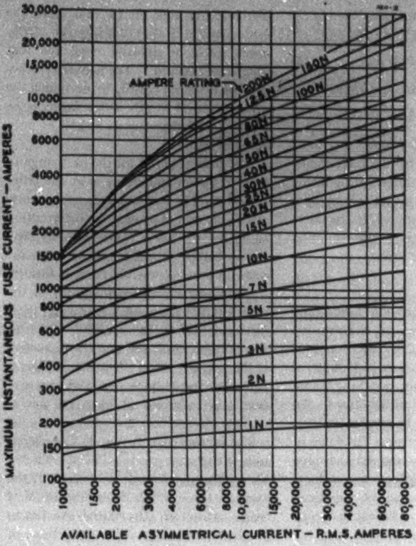

Figure 2. Maximum instantaneous current permitted by a line of current-limiting type fuses

the purpose of selecting permissible limits of switching surge voltage, safe practice will be adhered to by considering the crest value of the machine's one-minute high-potential test voltage as the maximum value of allowable transient voltage. The first logical limitation is then $\sqrt{2}(2E+1{,}000)$ where E is the rated terminal-to-terminal rms voltage of the lowest rated machine connected to the circuit in which the fuse is to be applied. For example, the limit for a 5,000-volt fuse is based on $E=4{,}000$ since this is the lowest rated machine in the 5,000-volt class. Since all other apparatus appears to have a higher insulation level than rotating machines, this limit should be entirely safe from a consideration of insulation alone.

A second and less obvious limit is imposed by the possibility of the operation of lightning arresters during voltage surges which would not damage insulation. The minimum 60-cycle spark-over voltage of an arrester is 1.5 times its maximum permissible line-to-ground voltage (proposed revision AIEE Standard 28) and its average spark-over voltage is somewhat higher. It is obviously desirable to minimize the number of arrester operations in all cases and to eliminate unnecessary operations wherever possible. Therefore, it becomes apparent that a desirable limit for switching surge crest voltages is 1.5 times the maximum crest rating of arresters used on the circuits for which the fuses are designed.

It has been found practical to design current-limiting fuses, as described later, to inherently limit switching surge voltages to magnitudes below the crest of the 60-cycle spark-over voltage of arresters which are rated above the voltage rating of the fuse. However, good engineering practice dictates the application of current-limiting fuses capable of interrupting line-to-line voltage whereas operating experience justifies the use of lower rated arresters on solidly grounded neutral systems. Therefore, since a line-to-line rated fuse may be expected to produce a switching surge voltage somewhat higher than the crest of normal line-to-line voltage, the associated line-to-neutral arrester is subject to spark over during every fuse operation. This condition does not exist when the fuses and arresters are *both* applied on the basis of line-to-line voltage.

When an arrester sparks over while a current-limiting fuse is interrupting a circuit, the two devices divide the dynamic short-circuit current in inverse proportion to their respective resistances. As previously pointed out, this current may be considerably higher than that ordinarily associated with switching surge voltages and its duration may be in the order of 1,000 to 1,600 microseconds. The ability of an arrester to pass current for relatively long periods of time is limited by economic considerations and this limit is recognized in AIEE Standard No. 28. It therefore becomes advisable to determine and assign interrupting ratings to fuses in a way that the short-circuit currents permitted by the fuses, when arresters are subject to spark over, are limited to values such that the arresters may safely pass their share of current without damage to the arresters.

From the considerations discussed above, it may be concluded that fuses of the current-limiting type should be so designed that switching surge voltages are inherently controlled to meet the following conditions:

1. The transient recovery voltage should not exceed the insulation level of rotating machines $\sqrt{2}(2E+1{,}000)$ where E is the rated terminal-to-terminal rms voltage of the lowest rated machine involved.
2. The transient recovery voltage should preferably not exceed the 60-cycle crest spark-over voltage of associated lightning arresters.
3. If the transient recovery voltage does exceed the 60-cycle crest spark-over voltage of associated arresters, the interrupting rating of the fuse should be determined and assigned to limit the arrester current to a safe magnitude.

Designing Current-Limiting Fuses to Control Switching Surge Voltages

One method of controlling transient recovery voltages to meet specified limits has been used for two years in commercially available fuses. It consists essentially, figure 1, of resistance wires, in parallel with the conducting wires, through which the energy of the surge is shunted and absorbed. The currents which the shunt-resistance wires must handle are shown as the ordinates of the curves of figure 2. The practical application of this principle appears to be limited to fuses rated approximately ten amperes and below as the required ability of the shunt-resistance wires to absorb surge energy increases rapidly as the continuous-current ratings of the fuses increase. Since the shunt-resistance wires occupy space and serve no useful purpose during normal current conditions, it is obvious that the fuses may be made smaller and less costly by combining the voltage limiting and current-carrying functions. This desirable result may be obtained by controlling the growth of arc resistance during the interrupting process. The conducting elements, schematically shown in figure 3, form a basis for the reliable control of arc resistance.

The resistance of an arc is a function of its diameter, length, and the magnitude of current in the arc. The voltage which appears across the fuse at any instant during current interruption is the product of the arc resistance and arc current at that instant. Neglecting other circuit resistance which may be present, this condition may be expected by the fundamental equation:

$$e = ri + L\frac{di}{dt} \qquad (1)$$

where

e = generated voltage
r = arc resistance
i = arc current
L = circuit inductance
t = time

Therefore, it is apparent that the rate and amount of arc resistance inserted in the circuit determines the rate of rise and magnitude of the transient recovery voltage.

When the available short-circuit current is of such magnitude that the current is appreciably limited by the fuse, it has been found empirically that the arc resistance of the fuse at the instant of surge voltage crest, is directly proportional to the arc length. The arc length at any instant is in turn equal to the length of the conducting element which has been volatilized. The number and diameter of the conducting elements volatilized also influence the arc resistance, at the instant of surge voltage crest, as indicated by the following empirical equation:

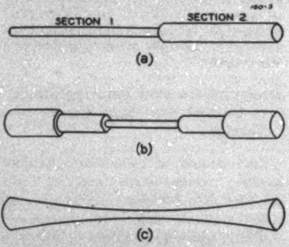

Figure 3. Conducting elements (schematic) showing use of progressive steps in cross section

$$r = [K_1 - (K_2 + K_3d^2)\sqrt{n}]l \qquad (2)$$

where

r = arc resistance at instant of surge voltage crest
d = diameter of conducting elements
n = number of conducting elements
l = arc length
K_1 K_2 K_3 = constants

The surge voltage crest may then be expressed as:

$$V = ir = i[K_1 - (K_2 + K_3d^2)\sqrt{n}]l \qquad (3)$$

Where i is the instantaneous current at surge voltage crest as given by the curves of figure 2.

Since the values of d and n are fixed within narrow limits by the continuous-current rating and the interrupting rating of any given fuse[4] and since the maximum value of i is also determined by the interrupting rating of the given fuse, equation 3 reduces to the simple form:

$$V = Kl \qquad (4)$$

The accuracy of equation 4 has been established by hundreds of comparative interrupting tests. This equation provides the basis for a new and effective method of controlling switching surge voltages of current-limiting fuses. To hold the crest voltage to a value V_1, it is only necessary to determine the value of K for the fuse rating concerned and solve equation 4 for the length of the conducting element, l_1, which may be vaporized at the time V_1 occurs. The length of conducting element so determined may be, and in most cases is, less than the minimum length required to safely interrupt the circuit. Therefore, it is necessary to provide additional conducting element length which, when vaporized, will produce sufficient additional arc resistance to effect interruption.

To prevent the crest voltage produced by the added length of element from superimposing itself on the first crest, the vaporization of the added length of element must be delayed until the first surge has declined. The necessary delay may be obtained readily by designing the added element length with a larger cross section than the original length as indicated in figure 3*a*.

The time required for the first surge to reach its crest and decay is in the order of 100 to 150 microseconds with short-circuit current at or near the interrupting rating of the fuse. This fact has been established by hundreds of short-circuit tests on fuses of various current ratings. Typical cathode-ray oscillograms of the transient voltage conditions during these tests are shown in figure 4. It may therefore be concluded that the diameters of the two sections of conducting element, figure 3*a*, should be so designed that section 2 is vaporized at least 150 microseconds after section 1.

The factors contributing to the magnitude of the surge produced by section 2 of the conducting element are essentially the same as those which determine the first surge. However, the initial conditions for the second surge differ from those of the first surge in that the short-circuit current has declined to a lower value and the initial voltage is at least equal to the normal frequency voltage at that instant. With these exceptions, the maximum length of section 2 may be determined from equation 4 with the proper evaluation of constants. The optimum element design is that which gives the minimum

A Vertical-Flow Outdoor Compressed-Air Breaker

L. R. LUDWIG

B. P. BAKER
ASSOCIATE AIEE

1. Introduction

THE elimination of oil in indoor circuit breakers, particularly for powerhouse use, has been insistently demanded to reduce fire hazard. In an effort to meet these requirements, various types of breakers not containing oil have been built and studied. Self-contained breakers of the "De-ion" type[1] have been available for several years, and the potentialities of water breakers[2] have been carefully investigated. Compressed-air breakers[3] for this service have been successfully developed, particularly to meet high kilovolt-ampere interrupting requirements, and the circuit-rupturing ability of these devices has been so amazingly efficient that experimental breakers using this principle have now been built and tested for high-voltage outdoor application.

2. Interruption With Compressed Air

Compressed-air breakers for interrupting medium powers have been in use in Europe for ten years, but these devices have not been available in America until recently. The longitudinal flow-type interrupter, generally used in Europe, was investigated and found to be very satisfactory for moderate values of current, but its inherent limitations made it impractical for the medium and high kilovolt-ampere requirements at powerhouse voltages. On the contrary, an interrupter using a blast of compressed air and insulating splitters disposed perpendicular to the arc, was found to be very effective and not subject to the same arc-current limitations. Structurally, it was also found well adapted for use with high-current carrying contacts.

Just one year ago, the $1^{1}/_{2}$-million kva, 15-kv compressed air circuit breaker[3] of the transverse-flow type was reported, and oscillograms of single-phase operations at 13.2 kv up to 65,300 amperes rms were shown. Since then, the same $1^{1}/_{2}$-million kva breaker has been successfully demonstrated at 13.2 kv, 3 phase up to 86,500 amperes, and this type of interrupter is now being built into a $2^{1}/_{2}$-million kva, 15-kv breaker for 4,000 amperes continuous current-carrying capacity. Currents in excess of 100,000 amperes can be interrupted with this breaker using tank pressures not greater than 150 pounds per square inch.

The theory of this interrupting process in breakers of this type has been studied. The effectiveness of the cross-blast, splitter-type interrupter appears to depend on, first, the fact that a number of interrupting elements or splitters can easily be used in series, and second, the use of a gas-forming material such as fiber for the splitter. The function of the gas-forming splitter elements is largely to introduce turbulence into the arc stream to enhance the deionization by diffusion, following a current zero. Slepian[4] has described this theory in detail.

As breaker voltages are increased from 15 kv or 34 kv, the problem of insulation becomes of increasing significance and it becomes more difficult to design a satisfactory structure which operates on the cross-blast principle. Fortunately, the currents to be interrupted decrease as the voltage increases but not to a sufficient extent so that plain metallic nozzle interrupters can be used with moderate air pressure. Consequently, for the higher voltages it has been necessary to develop a new type of interrupting element which lends itself to vertical porcelain-clad breaker construction and provides high-interrupting ability.

3. Vertical-Flow Compressed-Air Interrupter

The reasons cited for the success of the cross-blast interrupter suggest that a satisfactory form of device can be built for higher voltages by using fiber disks horizontally disposed. These disks have central orifices through which the arc is drawn and through which a vertical flow of air passes to effect the interruption. One or more of such elements can be placed in series, and a dual interrupter of this type is shown in figure 1. It consists of two fiber disks with a metal insert in the center. These inserts have centrally located holes which form the orifices. Between these orifice disks another

---

voltage at any instant during interruption. This condition exists, other factors being equal, when both surges reach the same crest magnitude.

The desired limit of switching surge voltage cannot always be met, and successful interruption obtained, by the simple two-section conducting element. In such cases, it is necessary to extend the same design principles to include multisection conducting elements similar to that shown in figure 3*b*. Carried to its logical extreme, this procedure would result in conducting elements characterized by a smooth taper as indicated in figure 3*c*. However, from practical economic and manufacturing considerations, these tapered elements cannot yet be justified.

Conclusion

The control of fuse switching surge voltages by the use of conducting elements with uniform sections of different diameters has proved both practical and flexible. Current-limiting fuses employing this principle have been designed and are now commercially available. Comprehensive tests have shown that these fuses consistently limit the switching surge voltages to magnitudes within the acceptable levels given in the first part of this paper.

insulating plate is introduced which restrains the random motion of the arc in the exhaust gas. The interrupter is symmetrical about this insulating plate so that the stationary contact and the upper orifice form one working unit. Likewise, the moving contact and the lower orifice plate form another. The contact members are hollow to permit a portion of the air blast to pass through them. The metal inserts in the fiber disks are used to lessen erosion and enlargement of the hole in the disks.

The air blast passes through the porcelain below the interrupter where part of it escapes through the lower working unit. The remainder passes through the tubes in the interrupter to the upper porcelain from which it escapes through the upper working unit. The air, as shown in figure 1, approaches the arc in a radial direction from between the orifice plate and the streamliner of the contact. Upon reaching the arcing space, it turns and flows vertically along the arc stream, some of it escaping through the contact, while the greater portion escapes through the orifice plate.

It has been found experimentally that this combination is better than a solid conductor and an orifice, or two orifices with equal discharge area. The unsymmetrical flow of air serves to eliminate a "dead spot" in the center which is not readily deionized, and likewise the arc terminal is carried into the hollow of the contact, so that the flow of air carries the metallic vapor from the arc terminal out into the vent instead of into the restricted portion of the arc path where the growth of dielectric is the greatest. The smaller quantity of gas which is discharged through the contacts escapes out the top of the breaker and into the mechanism box. The greater amount which passes through the orifices escapes radially between the orifice plates and is cooled by the screening placed in the annular space formed by the two orifice plates, the air tubes, and the pin supports.

This very simple arrangement gives in reality two interrupting or working combinations in series. The first, consisting of the stationary contact and the upper orifice, which becomes effective with the first third of the contact motion.

4. 138-Kv Compressed-Air Breaker

Figure 2 shows both a photograph and a schematic diagram of a single-pole unit 138-kv experimental breaker. The usual air storage tank is mounted in a simple frame which also houses the electrical relaying equipment, blast valve, and valves to supply air for opening and closing the breaker. The air-blast valve is mechanically interlocked with the opening valves so that the contacts cannot part without sufficient air for arc extinction. The operating valves are also interlocked pneumatically so that the opening operation always takes preference over the closing operation. The blast valve located adjacent to the tank discharges into a hollow porcelain insulator which carries the air direct to the interrupter chamber with a minimum of length and turns. The operating mechanism is at line potential when the isolating disconnect switch is closed and engaging the current transformer or the top of a post insulator which forms the one line terminal. The other line terminal is at the top of the breaker. The interrupting element is halfway both electrically and mechanically between the top terminal and the operating mechanism. When the breaker is in the open position, the disconnect removes potential from the interrupter and short-circuits it by engaging suitable clips at the

top. The disconnect is mechanically interconnected to the interrupting contact and both are operated by an air piston moving in a cylinder located in the pole-unit mechanism box. Air for operating this piston is transmitted from the tank through valves at ground potential, and thence through hollow porcelain insulators, one for closing and one for opening. These two porcelains with the third and larger one which carries the air blast from the tank to the interrupter, form a supporting tripod and the insulation to ground. The mechanical linkage between the operating cylinder, interrupting contacts, and disconnecting member are such that in normal service the disconnect opens last on an opening operation and closes first on a closing operation.

The interrupting contact consists of a simple rod which slides within two tulip-type contacts, one supported from the mechanism box and the other from the top of the breaker, both extending toward the interrupting element which is centrally located. The arc is drawn from the upper stationary contact, downwardly through the interrupter, where it is subjected to the air blast.

The breaker is ideal for high-speed reclosing duty because of efficient disposal of ionized gases from the interrupter and the high mechanical speed of the air-operating mechanism. In case of reclosure, the disconnecting switch is not opened; the contacts are simply parted in the air blast, the arc is interrupted and the contacts are reclosed before the air blast is turned off.

This type of construction provides porcelain insulation to ground of the current-carrying parts and air isolation between terminals when the breaker and disconnect are in the open position. There are no heavy operating rods with potential across them, since the entire mechanical effort is transmitted through the medium of air flow in the porcelain columns. Contacts, interrupter, and mechanisms are very accessible and easily maintained. Provision for a porcelain-

clad current transformer is made on the disconnect end of the breaker. The pole units of a three-phase breaker are separate and distinct, and may be arranged for individual phase operation if desired. On the other hand, co-ordination of the three poles is possible by interlocking the air valves in obvious ways.

5. Experimental Test Results

Tables I and II show the results of two typical series of single-phase tests on the single-pole unit, 138-kv compressed air circuit breaker shown in figures 1 and 2. The highest of these tests represents power equivalent to slightly in excess of 2,000,000 kva on the basis of an ungrounded three-phase 138-kv system. The current on this film (figure 3) was unsymmetrical and thus contained considerable d-c component. On the basis that 127 kv is the line-to-neutral voltage of a grounded neutral system, the three-phase power equivalent is over 3,250,000 kva.[5,6]

Table I shows the results of a series of 18 tests at 132-kv applied voltage on the single-pole unit, 138-kv breaker at current values between 270 and 8,900 amperes. The restored voltage varied from 132 kv to 121 kv. The air pressure in the storage tank of the breaker varied from 210 to 230 pounds per square inch. The arcing time varied from 0.6 to 2.1 cycles. This variation indicates that in many of the operations even at 132 kv, the interruption was completed in the upper working unit without waiting for the arc to be drawn into the lower one. Figure 3 shows three typical oscillograms; one at 2,520, 5,840, and 8,900 amperes respectively. From the travel wave it is apparent that the 8,900 amperes was interrupted in the upper working unit which consists of one orifice and one contact, spaced less than one inch apart. Figure 4 shows the three cathode-ray oscillograms corresponding to the magnetic oscillograms in figure 3. The highest oscillatory frequency shown is 4,310 cycles per second, which occurred on the 8,900-ampere test. This corresponds to a recovery rate of 2,970 volts per microsecond. However, in table I frequencies as high as 4,620 cycles per second, or 3,180 volts per microsecond are recorded.

Table II shows the results of a series of tests at 66 kv and current values varying from 2,800 amperes to 13,900 amperes. Again all tests were single phase on the single-pole 138-kv unit shown in figure 2. The air pressure in the breaker storage tank varied from 210 to 230 pounds per square inch. The arcing time varied from 0.7 to 1.2 cycles. In all cases the circuit was interrupted without assistance from the lower working unit. Figure 5 shows the magnetic oscillograms for tests 1, 3, 5, and 7 of table II. Figure 6 shows the cathode-ray oscillograms corresponding to the magnetic oscillograms in figure 5. The oscillatory frequency of the 66-kv circuit was considerably higher than that of the 132-kv circuit. As recorded, these values varied from 3,270 to 9,780 cycles per second. This frequency resulted in a recovery rate which varied from 1,225 to 3,570 volts per microsecond, which is slightly in excess of that obtained on the 132-kv circuit when adjusted for minimum impedance.

Figure 7 shows the magnetic oscillogram of the upper working unit of the 138-kv breaker interrupting low current at 180 kv. Also, successful interruption of low values of current on a highly inductive circuit has been obtained up to 264 kv, but not until the arc was drawn into the second or lower working unit.

Figure 8 shows the magnetic oscillogram of the 138-kv pole unit interrupting the magnetizing current of two single-phase power transformers in parallel, each connected for 13.2 to 132 kv, 3.3 per cent impedance and 33,333 kva, giving a total current for both transformers of approximately 20 amperes. The circuit consisted of a 13.2-kv genera-

tor feeding a 13.2 to 132-kv transformer. In series with this transformer was the test breaker and the 132-kv windings of the unloaded transformers just described. Tests were made both with one and with two transformers for the load. In all cases the current was interrupted promptly in about one-half cycle, as shown in figure 8.

6. Conclusions

The general acceptance in this country of compressed air as an interrupting medium for low-voltage heavy-duty powerhouse breakers has stimulated interest in its application to outdoor high-voltage breakers.

Experimental evidence has shown that while the continuous current-carrying requirements and heavy interrupting duty of powerhouse breakers dictate a design using splitters and transverse flow, the vertical-flow type of interrupter may be employed to advantage for porcelain-clad outdoor high-voltage breakers.

Tests on a new type of vertical-flow interrupter indicate that it can be developed to handle the maximum kilovolt-ampere requirements at 69 kv and above. A comparison of table I and table II suggests that if approximately 14,000 amperes at 68 kv and 5,370 volts per microsecond can be successfully handled on one-half of the interrupter, currents considerably in excess of 8,900 amperes at 132 kv may be expected to carry this type of interrupter far into the future kilovolt-ampere requirements.

Development of the Glow-Switch

R. F. HAYS
ASSOCIATE AIEE

THE glow-switch[1] is an automatic switch for starting fluorescent lamps.[2] It is unique in that it is a thermal switch without a heater element, the heat being supplied by a glow discharge. The glow-switch functions as a time-delay relay yet it is a single-element switch with only two leads. At one value of applied voltage its resistance becomes a fraction of an ohm, while at a voltage only slightly lower, its resistance is measured in megohms. Before proceeding with the story of the development of the glow-switch, it is in order to discuss briefly the task which it performs.

Once the discharge is started, a fluorescent lamp can be operated from an a-c supply whose voltage is approximately twice lamp voltage. The lamp must be operated in series with an impedance, usually an inductance, to limit the current.[3] The most commonly used circuit is shown in figure 1. A voltage considerably higher than the supply voltage is necessary to start the discharge. The discharge should not be started until after the lamp cathodes have been heated to a temperature at which they can emit the necessary supply of electrons without entailing excessive positive ion bombardment. The glow-switch serves to automatically connect the lamp cathodes in series until they are heated to operating temperature, and then to break the connection, and subject the lamp to a transient voltage sufficiently high to start the discharge.

The glow-switch, figure 5, consists of a glass bulb, filled with an inert gas and containing a pair of contacts operated by thermostatic bimetal. Initially the contacts are open and the supply voltage appears across the switch. The supply voltage is sufficient to establish in the switch a glow discharge which heats the bimetal and causes the contacts to close. The current passed by the glow discharge is only a few milliamperes and does not cause any appreciable heating of the lamp cathodes, but when the contacts close, the current is limited only by the series inductance and the resistance of the cathodes. The cathode-heating current is approximately $1^1/_3$ times normal lamp current and it quickly heats the cathodes to operating temperature. While the contacts are closed, the glow discharge is extinguished so that the bimetal cools and after a short-time delay, during which the lamp cathodes are heated, the contacts open. Opening of the contacts suddenly interrupts the current and induces in the series inductance a transient voltage sufficiently high to start the arc through the lamp. After the lamp is started the cathodes are self-heating and the voltage across the lamp is insufficient to re-establish the glow discharge in the switch. The contacts remain open and the switch consumes no energy. If for any reason the lamp does not start the first time the contacts open, the cycle is quickly repeated.

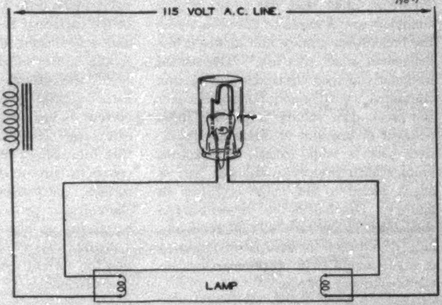

Figure 1. Fluorescent lamp circuit

The requirements that must be met by the glow-switch are as follows:

(1). The breakdown voltage for the glow discharge must be less than supply voltage and greater than lamp voltage.

(2). The contacts must close quickly.

(3). The contacts must remain closed for a period of time sufficient to allow the lamp cathodes to reach operating temperature.

(4). The switch must interrupt the current quickly so that the transient voltage induced in the series inductance will be sufficiently high to start the lamp.

(5). The switch must be small and inexpensive.

Breakdown Voltage

The breakdown voltage, or the voltage at which the glow discharge starts, must be less than the lowest supply voltage with which the glow-switch is to be used, and must be safely above peak lamp voltage so that the switch will not glow and the contacts will not close after the lamp starts. The *T*-12, 15-watt, the *T*-8, 15-watt, and the *T*-12, 20-watt lamps operate at 48, 56, and 62 volts respectively, and all three lamps are for operation from a supply of 118 volts ± 10 per cent. The same glow-switch is used with all three lamps. The voltage wave form for a fluorescent lamp is nonsinusoidal, and at low current the voltage is abnormally high. The peak voltage for a 20-watt lamp operating from minimum allowable supply voltage is equal the peak value of a sinusoidal voltage of 70 volts. Accordingly, the minimum breakdown voltage was set at 75 volts alternating current, and the voltage necessary to start the glow discharge and cause the contacts to close in a reasonable time was set at 105 volts.

It was found that neon containing a small amount of argon, used with electrodes coated with magnesium, gave a minimum breakdown voltage just greater than the minimum allowable limit. The breakdown voltage should not vary greatly with respect to gas pressure, gas mixture, or electrode separation, so that reasonable tolerances can be allowed in manufacture, and so that breakdown voltage will be relatively independent of pressure changes due to gas cleanup during the life of the switch. Figure 2. Break-down voltage

With respect to gas pressure and electrode separation for (*A*) parallel plane electrodes, and (*B*) irregularly shaped electrodes (Slepian)

figure 2 shows how breakdown voltage varies with respect to the product of gas pressure and electrode separation for a glow discharge between plane parallel electrodes.[4] Curve *B* shows the effect of a nonuniform field obtained by using electrodes of irregular shape. Fortunately, a nonuniform field makes the break-down voltage less dependent upon the product of pressure and electrode separation at values greater than that corresponding to minimum breakdown voltage. Figure 3 shows that the addition of a small amount of argon to the neon lowers the breakdown voltage and makes it less dependent upon pressure.[5] The use of irregularly shaped electrodes and of neon containing a small amount of argon makes the breakdown voltage practically independent of pressure or electrode separation over a wide range. Breakdown voltage with respect to the per cent of argon added to the neon[5] is shown in figure 4. One-half of one per cent argon was added to the neon so that relatively large deviation from the specified amount of argon would have no serious effect on the breakdown voltage.

Fast Closing of the Contacts

The contacts can be made to close quickly by the use of a sensitive bimetal element, by using closely spaced contacts, by using a bimetal element with minimum heat capacity, and by producing a high-current density at the surface of the bimetal when it serves as cathode for the glow discharge. Sensitive bimetal and close contact spacing result in closure of the contacts upon a slight rise in temperature. The temperature of the bimetal necessary for closing the contacts should be as high as 100 degrees centigrade, so that operation will be relatively independent of room temperature. A sensitive bimetal element is necessarily long and thin, and consequently, the force per unit deflection of the contact is small. If the bimetal element is sensitive and the contact spacing is small, there will be little force available to pull the contacts apart when they stick. The bimetal should be short and only as thick as necessary to obtain the required rigidity so that the heat capacity will be low. The most desirable method of increasing speed of operation is that of increasing the current density.

For a normal glow discharge the cathode-voltage drop and the current density at the surface of the cathode are constant, and the current density is proportional to the square of the gas pressure. The size of the cathode spot increases, but the cathode drop remains constant as the current is increased until the cathode is completely covered by the glow. Further increase in current demands an increase in current density at the cathode surface, and causes an increase in cathode-voltage drop. Such a condition represents an abnormal glow discharge.

Slepian[4] has given the following equation for current density for an abnormal glow discharge:

$$J=J_0+K(E-E_0)^2P^2 \qquad (1)$$

$$J_0=BP^2 \qquad (2)$$

where J is current density; J_0, normal current density; E, cathode drop, E_0, normal cathode drop; P, gas pressure; and B and K are constants. This equation shows that to cause rapid closing of the contacts by producing a high-current density, the gas pressure must be high, E_0 must be as low as permissible, and E must be high. For a neon-argon mixture in a nonuniform field, and PD greater than the critical value, E_0 is practically equal the breakdown voltage, the value of which has already been determined. E is equal the supply voltage minus the IZ drop in the inductance and the lamp cathodes. Obviously, E will be a maximum only if the current drawn by the glow discharge is a minimum. A high-current density and yet a small current can be obtained only by the use of a small cathode-surface area. Then, for rapid closing of the contacts, the gas pressure must be high, and the bimetal element must be as small as is practical from the standpoint of manufacture.

Time Delay

The contacts must remain closed for a period of time sufficient to allow the lamp cathodes to reach operating temperature. For 15- and 20-watt fluorescent lamps this time is approximately one second. The time delay is produced by the inevitable sticking of the contacts and by nonuniform heating of the bimetal, which results from the use of high gas pressure.

Transient Voltage for Starting the Lamp

When the contacts open, there must be induced in the series inductance a transient voltage of sufficient magnitude and duration to start the lamp. It is impos-

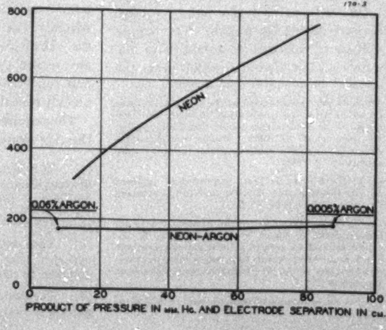

Figure 3. Break-down voltage

With respect to gas pressure and electrode separation for pure neon and for a mixture of neon and argon (Penning) sible to interrupt a current through an inductance instantaneously. For an instant after the contacts open, the inductance forces the current to continue flowing at a value practically equal to that of the instant before the contacts opened. The current continues to flow and decreases in magnitude as the energy stored in the magnetic field of the series inductance is dissipated. Then, until the lamp starts, the voltage across the glow-switch and across the lamp is the voltage corresponding to the current flowing through the switch whose contacts are open. Current can continue flowing through the switch after the contacts separate because of arcing at the contacts and re-establishment of the glow discharge. As the contacts separate, the current is carried by one point on each contact and the temperature of these points reaches the value which Slepian[6] has shown to be equal

$$T = \frac{E^2}{33.5kp} \tag{3}$$

where k is the thermal conductivity of the contact material (calories/centimeters squared/degrees centigrade/centimeters) and p is the electrical resistivity of the contact material (ohms/centimeters cubed). Copper contacts interrupting a one-volt circuit reach a temperature of approximately 4,000 degrees. Obviously, there is no metallic contact material available which will not melt and vaporize at the voltage to be used. Arcing at the contacts is supported chiefly by thermionic emission from the hot points and by thermal ionization of the hot vapor emitted from the points. Arcing can be kept at a minimum by using contact material which evolves a minimum amount of vapor. Tungsten makes an ideal contact because of its high work function, high melting point, low vapor pressure even in the molten state, and high resistance when hot. The current due to arcing at the tungsten contacts is negligible compared with that due to re-establishment of the glow discharge. Therefore, the transient voltage is practically equal the voltage across the glow discharge corresponding to the instantaneous value of current through the circuit.

Figure 5. The glow-switch, assembly of glow-switch and capacitor for suppressing radio interference, and the complete starter unit

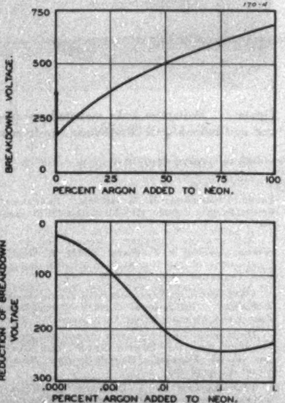

Figure 4. Minimum breakdown voltage for neon with respect to the percentage of added argon (Penning)

Rearrangement of equation 1 shows that the voltage across the glow discharge is equal

$$E = E_0 + (J - J_0)^{1/2}\frac{K}{P} \tag{4}$$

where

$$J = \frac{i}{A} \tag{5}$$

Equation 4 shows that the transient voltage can be made high by the use of low gas pressure. It has already been shown that the pressure must be high if the contacts are to close quickly. A compromise must be made. The pressure should be made only as high as is necessary for the contacts to close in a reasonable length of time; say, one or two seconds. Even so, the transient voltage is not always high enough to insure reliable starting of the lamp. Since E_0 and J_0 have already been fixed, the only other expedient is to increase the value of J.

Equation 5 shows that J can be made large by reducing the value of A. Fortunately, as has already been shown, A, the surface area of the cathode for the glow discharge, should be small to permit quick closing of the contacts. With the bimetal as small as is practical from the standpoint of manufacture, its surface area is still too large to insure reliable starting of the lamp. It is necessary further to increase the value of J by using only one strip of bimetal and letting the other electrode for the glow discharge consist of only a short lead wire with a contact welded to it. The surface area of this short lead wire and contact can easily be made very small. Of course, the highest transient voltage is produced only if at the instant the contacts separate, the current is flowing in the direction that will cause the small surface area electrode to serve as cathode for the glow discharge. The fact that there is only a 50 per cent probability that the highest transient voltage will be produced is not considered objectionable because, if the voltage is insufficient to start the lamp, the energy stored in the series inductance is instantly dissipated in the glow switch, and the contacts immediately reclose to repeat the cycle. The value of the series inductance has little effect upon the magnitude of the transient voltage but does affect its duration. Equations 4 and 5 are only approximately true[7] because the transient voltage varies too rapidly for the glow discharge to reach equilibrium. However, they show what steps must be taken to improve the characteristics of the switch.

Conclusion

It has been shown that for proper operating characteristics, the glow-switch necessarily must be small. The small size and simple construction of the switch as shown in figure 5 lend it to economical production on automatic machinery.

A glow-switch will start a lamp under normal conditions approximately a mil-

The Protective Link

J. K. HODNETTE
MEMBER AIEE

M. G. LEONARD
ASSOCIATE AIEE

Synopsis: The protective link is a device recently developed for internal mounting in transformer of a wide variety of types and ratings. Its most common application, however, is in distribution transformers where it serves to disconnect the transformer in case of internal fault. Its action in arc extinction depends on a number of factors including a novel arrangement of the lower terminal which allows it to be expelled from the link when heavy currents are interrupted.

Although simple and compact, the link is a very efficient arc-quenching device, and has a remarkably high-circuit interrupting capacity combined with high speed of operation. Power arcs of more than 250,000-kva single phase have been interrupted in one-half cycle.

Introduction

SOME form of circuit-opening means has been used with transformers from the very beginning of the a-c system for the purpose of protecting the line or system against an extended outage in case of damage to an individual transformer. Economic factors in general have dictated the kind or type or the extent of the protection. Large important substations are protected with circuit breakers and differential-transformer protection to remove quickly a faulted transformer. Less important substations are protected by circuit breakers actuated by overcurrent or ground relays, and finally where circuit breakers cannot be justified from the standpoint of cost, high-voltage fuses are used to protect smaller substations, transformer banks, and individual transformers. Recently protective links have been applied to transformers for a similar purpose. They have been used on a wide range of ratings, but it is in the distribution range where they have found most of their application up to the present time.

In this application they are used in conjunction with circuit breakers to permit loading the transformer to its maximum safe copper temperature regardless of the amount or duration of load. The link alone, though designed for long-time lag, will not serve this purpose, because of the extremely long time constant of the transformer. The circuit breaker, on the low voltage side, follows this characteristic of the transformer and effectively prevents it from burnout because of overload. The protective link, on the high voltage side, protects the line from outage which might occur in case of failure within the transformer. In this function, its construction and mounting provide a number of inherent advantages. It is electrically protected against false operation by the transformer breaker on the one side and by sectionalizing or line breakers on the other. It is mechanically strong, and resistant to the action of transformer oil. Because of its internal mounting it is not exposed to weathering, and because of its electrical connection at the transformer bushing it is not subjected to lightning surges. These factors are especially important on the smaller ratings where the physical size of the fusible element is necessarily very small.

Description of the Protective Link

The appearance of the link as used in distribution transformers is shown in figure 1. This shows a core and coil assembly with a protective link mounted at each side of the porcelain tap-changer block. When assembled in the transformer, the high-voltage bushing lead runs directly to the top terminal on the link, thus placing the link electrically ahead of any fault which may occur either in the coil or the tap changer. The link itself is shown in section in the drawing of figure 2. It is simple in construction, consisting essentially of a fusible element enclosed in an insulating tube with a fixed and a movable terminal. The movable terminal, mounted at the

---

lion times, so that its life ordinarily should be very long. However, when a lamp fails, the switch keeps operating in an attempt to start it. Under failed lamp conditions, the life of the switch is approximately 100 hours.

In addition to starting lamps under conditions which insure good lamp life, the glow-switch has a number of advantages over other types of starters. It is operative over a wide range of current and compared with other types of lamp starters, it has a very long life under failed lamp conditions. Because the glow-switch is a two-wire device, it reduces wiring to a minimum. Simplified wiring permits placement of the glow-switch in a removable capsule which fits into an extension of the fluorescent lamp socket. Field results with the glow-switch, since its introduction two years ago, have been very satisfactory, and at present there are approximately six million glow-switches in use.

lower end of the tube, is one of the new features of this design, and plays an important part in extinguishing the arc, as explained below. The fusible element consists of a mechanically strong wire which is chemically neutral in transformer oil and resistant to corrosion; these properties are essential to insure stability of the fusing characteristic over a long period of time. The fusible element is composed of copper, or, for the smaller size, a high-resistance copper alloy. The fusing temperature is much in excess of the boiling temperature of the oil. This is an important characteristic, for it tends to reduce the damage to the link caused by momentary overcurrent, and provides a means for control of the fusing-time curve of the link as described below.

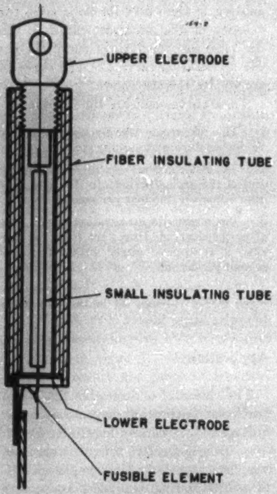

Figure 2. Section through protective link

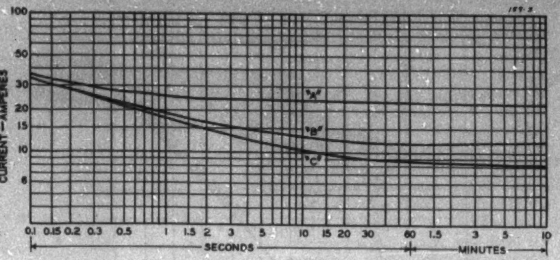

Figure 3. Fusing characteristic of protective links

(*a*)—Bare conductor in oil
(*b*)—Small insulated tube over conductor
(*c*)—Small insulated tube over conductor and gas entrapped within link

Surrounding the fusible element (figure 2) is a small insulating tube, the purpose of which is to retard the flow of heat from the wire. When a current slightly above the minimum fusing value is passed through the wire, its temperature is increased depending upon the rate of heat generation in the conductor and the rate of heat dissipation into the oil. With the current constant, the temperature increases approximately exponentially until the boiling temperature of the oil is reached. The chemical change in the oil under these conditions greatly increases the rate of heat dissipation of the oil. As a result, little further change in temperature results until the distillation gases sufficiently blanket the conductor. The temperature again increases approximately exponentially until the fusing point is reached.

If a bare conductor placed in the oil were to be used as a protective link, the gases distilled from the oil would escape freely and the current-time fusing characteristic of the conductor would be quite flat as shown in curve *A*, figure 3. By surrounding the link with a small insulating tube, the distillation gases quickly displace the oil in the tube and it then effectively insulates the conductor and retards the heat flow. This reduces the current and the time required to fuse the conductor for all ranges of current and time beyond that where all heat is stored in the conductor. An example of the reduction in current is shown in curve *B*, figure 3. By controlling the blanketing action of the distillation gases, the shape of the current-time curve can be adjusted to the desired shape to co-ordinate most effectively with other current-limiting devices on the system. The maximum blanketing occurs when the conductor is entirely surrounded by a gas (curve *C*, figure 3).

With the present knowledge of the impulse characteristics of transformer insulation and with modern lightning protective devices arranged for balanced lightning protection, major insulation failures from lightning have been practically eliminated. Therefore, line-to-line or line-to-ground failures of transformers in service, which would make it necessary for the protective links to open the full short-circuit current of the system, are uncommon. To insure successful operation, however, the protective links should be selected with sufficient arc-interrupting capacity to interrupt the current resulting from a short circuit across the terminal board of the transformers.

This, as mentioned, is not the usual condition. One of the most usual causes of transformer failure is short circuit in one of the windings between turns or between coils. Under these conditions, the fault current builds up spasmodically with a rush of current as each new element of the winding is involved in the failure. Since a considerable portion of the trans-

Figure 4. Oscillogram of protective link operation showing

(*a*)—Voltage across link

(*c*)—Timing wave
(*d*)—Position indicator wave

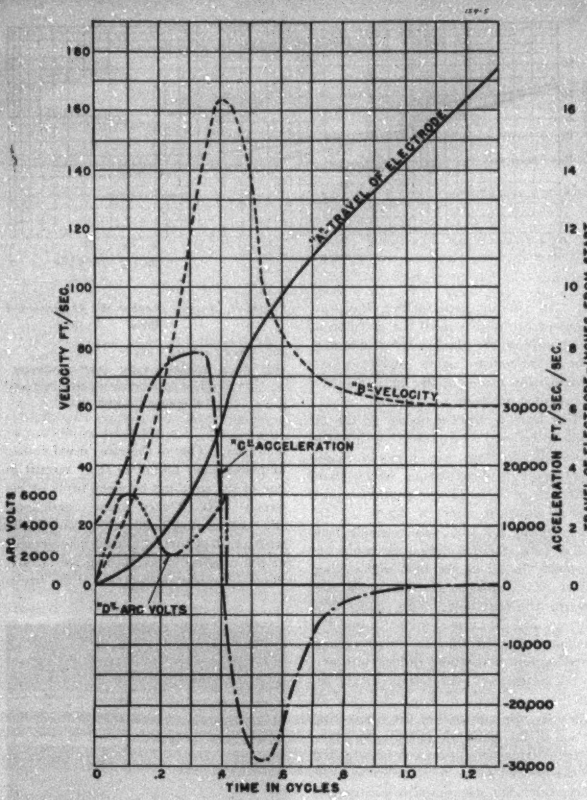

Figure 5. Analysis of electrode travel during arc interruption

former-winding impedance remains in series with the fault, the current builds up to a value sufficient to blow the protective link but does not approach system short-circuit proportions.

At the time of trouble in actual service, when the current reaches a value sufficient to fuse the link, an arc is formed in the oil inside the fiber-insulating tube. A high pressure is immediately developed inside the tube which increases the arc-voltage drop and aids in quenching the arc. This high pressure drives the lower electrode violently from the tube as if by explosive action. The arc trailing after it passes from the high-pressure area inside the tube to an area of comparatively low pressure outside the tube. This is an area of violent turbulence which is effective in arc quenching, principally because of the diffusion of the oil into the gas bubble surrounding the arc. Finally, the movable electrode moves rapidly through the oil stream tending to "neck" the arc and quench it.

Interruption of fault current occurs usually at the first current zero after the arc has been struck. The rapid movement of the free terminal through the oil builds up a layer of fresh oil between the moving electrode and the gas bubble after current zero, which effectively prevents restriking. Mounting the link in a vertical position so that the free electrode moves downward aids in this respect since the gas bubble is displaced upward by the pressure of the oil.

In order to investigate the action which takes place during the operation of the protective link, a special test was set up. A link was made in which the lower electrode was carried on a light but rigid arm. This arm was pivoted at one end, to allow the electrode to swing down freely as it does when attached to a flexible cable. A commutator device was mounted on the arm to permit recording of its position on an oscillograph.

The action of the link in interrupting the arc and a conception of the speed and the forces involved can be obtained from the results of this test as shown in figures 4 and 5. Figure 4 is an oscillogram of an interruption of a circuit connected for 1,500 amperes and 22,000 volts. It shows the normal operation of clearing the circuit in one-half cycle, and also shows very clearly the eight make-and-break points obtained by the commutator (curve *D*, figure 4).

From these data, a curve of position of the electrode against time is obtained, as shown in figure 5, curve *A*. Graphical analysis of this curve for slope gives the velocity of the electrode, curve *B*. In the same way, analysis of curve *B* gives the acceleration curve *C*. The curve of arc voltage *D* is also shown.

These curves indicate the following:

1. The electrode travels approximately six inches during the arcing period.
2. The maximum velocity is reached at the end of the arcing period; in this case it is approximately 165 feet per second.
3. The maximum acceleration occurs just after the electrode leaves the tube; in this case it is approximately 40,000 feet per second per second.
4. The electrode travels approximately eight inches through oil in the half cycle following the extinction of the arc.

Application

The choice of a protective link for a particular application depends upon the voltage and the current to be interrupted. The simple link shown in figure 1 has been supplied extensively to a completely self-protected distribution transformer, and other distribution transformers exposed to severe lightning conditions. Its interrupting ability is adequate for practically all applications for transformers up to 100 kva and 15,000 volts. These links will interrupt successfully 12,000 to 20,000-kva single phase in the above voltage range.

For larger units in the range of approximately 20,000 to 75,000-kva single-phase interrupting capacity, a longer and stronger fiber tube is necessary. A protective link of this type is shown in figure 6. The general construction remains the same. It will be noted, however, that the lower electrode is not attached to the tube, but is suspended from the fixed

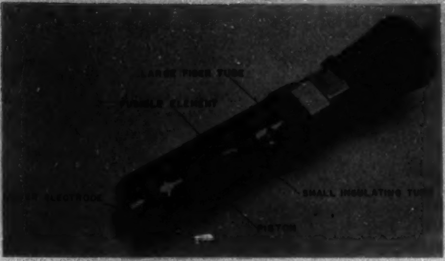

Figure 6. Protective link for application to power transformer

electrode. A piston of insulating material is used to transmit the mechanical impulse to the movable electrode. Protective links of this rating have been applied to completely self-protected power transformers in sizes up to 3,000 kva and 33,000 volts.

Another interesting application is to subway distribution transformers. Links with an arc-interrupting capacity of 10,000 amperes were applied to 2,400-volt subway transformers. These transformers were equipped with thermally-operated breakers in the secondary, properly coordinated with the protective links and arranged to protect the units against burnout from overload and secondary short circuit. The use of the protective links together with a disconnecting-type, high-voltage cable connection made the unit self-contained and very easy to install.

For application to still higher capacity circuits, the protective link is modified as shown in figure 7. Means are provided to reduce the pressure produced inside the tube and to increase the arc-quenching action at low currents and high voltages. The reduction in pressure is accomplished by enlarging the space above the main insulating tube and mounting inside it a shock-absorbing device. This device consists of a thin-walled cylindrical ring filled with gas under atmospheric pressure. Under high-current operation, the walls of the gas container collapse and cushion the pressure wave, thereby reducing the mechanical shock and the internal pressure in the device.

Interruption of low currents at high voltage is accomplished by means of the small auxiliary fiber tube. This tube creates a high-pressure zone immediately surrounding the arc, making it effective for currents as low as the exciting current of the transformer. At high current this tube is ruptured.

Links of the type as shown in figure 7 are applied to transformers with voltage ratings up to 69,000 volts. They have been tested at power levels of more than 250,000-kva single phase. An example of this is shown on the oscillogram of figure 8.

Field Experience

Within the last few years many thousands of protective links have been placed in service in distribution transformers. Some of these have had occasion to operate either because of a defect in the winding causing coil failure, or because of low electrical clearance at some point causing breakdown on surge. In most cases the lower electrode was driven from the end of the tube. Occasionally, when the current was only slightly above the minimum required to fuse, the arc was quenched before the electrode was dislodged. Usually the electrode was found to be driven out violently; in fact the evidence of the violence of this action is some indication of the magnitude of the current interrupted. But even when severe mechanical damage was done, the link served to clear the circuit, and the small amount of burning on the electrodes showed that the arc was extinguished quickly.

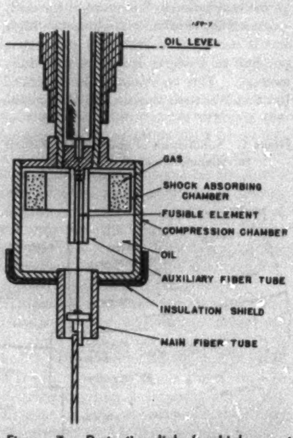

Figure 7. Protective link for high-current and high-voltage interrupting capacity

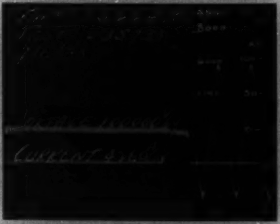

Figure 8. Oscillogram of protective link operation for link shown in figure 7

A case of operation on power transformer has occurred. Links were applied to the high-voltage side of a 33,000 to 4,160 volt, 1,000-kva 3-phase unit, and a breaker was connected on the low-voltage side. This breaker was rated at 5 kv, and protected by 33-kv links connected in series. This was considered desirable because high- and low-voltage lines were carried on the same pole. Shortly after this unit was put into operation, a wind storm blew off a sheet metal roof from a barn which struck the line, broke the high-voltage wires and caused them to fall across the low-voltage line. The breaker opened, but was not able to clear the high-voltage arc, which burned across the open contacts until the protective links cleared the circuit. Two of the links on the low-voltage side and one on the high-voltage side were blown during this disturbance. Except for the burning of the breaker contacts and adjacent parts, no damage was done to the unit. After reloading the links, the transformer was put back on the line and has since functioned satisfactorily.

Variations of Atmospheric Temperature With Altitude in the United States

H. W. TENNEY
MEMBER AIEE

IT has long been recognized that with increase in altitude the density of air decreases and influences the voltage rating and temperature rise of electrical apparatus. However, different standards for apparatus do not give the same weight to these factors. Examination of Weather Bureau data shows that there is a decrease in average atmospheric temperature with altitude, which should compensate to some extent for the influence of the decrease in air density on the rate of cooling at higher altitudes. This led to a study of temperature records of the United States for the purpose of presenting a summary of the variation of mean temperature with altitude.

The Weather Bureau of the United States is to be complimented on the fund of data which it has collected and the usable form in which it is available. The chief source of data used in this paper is the 1938 issue of Climatological Data for the United States.[1] In this issue there are temperature data from 3,119 stations for the year 1938 and the departure of the annual mean temperature from the mean of the temperature for all years of record. Consequently, by algebraic subtraction of the departure of the mean for 1938 from the annual mean, the mean temperature for the period of record is obtained.

The daily maximum and minimum temperatures are read from properly exposed thermometers at the co-operative observation station. At the first-order Weather Bureau stations thermograph charts are taken, giving continuous record of temperature variations. The records made by co-operative observers of the Weather Bureau, which are used largely in preparing charts and drafts, are made with standard maximum and minimum thermometers exposed in approved shelters, usually at an elevation of five feet above the ground. The true average daily temperature corresponds closely to the average of 24 hourly observations, but as several other combinations of hourly values give averages that differ but little from the true daily average some one of these is generally used to reduce observational work. The combination—

$$\frac{(7\text{ a.m.}+2\text{ p.m.}+9\text{ p.m.}+9\text{ p.m.})}{4}$$

gives a value which differs only slightly from the true daily average, and

$$\frac{(\text{sunrise}+2\text{ p.m.}+9\text{ p.m.})}{3}$$

also gives fairly accurate results. The formula

$$\frac{(\text{maximum}+\text{minimum})}{2}$$

is easy of application and very satisfactory when dependable maximum and minimum thermometers are used and properly exposed. The mean of the daily extremes is, as a rule, slightly too high, but it usually does not vary more than one-half of a degree from the true daily average. This combination is employed by the Weather Bureau to obtain the average daily temperature, and the data for the accompanying charts and diagrams were compiled by its use.[2]

A superficial analysis of some data indicated that the variation of temperature with altitude at the same general altitude differed with the watershed, as, for example, the eastern and western watersheds of the Allegheny Mountains in Pennsylvania. Therefore, in this analysis the country was divided into six districts as shown on the map, figure 1, as follows:

District No. 2—North Central United States (Mississippi Watershed).

District No. 3—Northern Rocky Mountains and Western Seaboard.

District No. 4—Southern Atlantic Seaboard.

District No. 5—South Central United States (Mississippi Valley).

District No. 6—Southern Rocky Mountains.

In order to simplify the analytical work, the border lines of the districts, in most instances, have followed the border lines of the several states included in each. While this makes for odd-shaped districts, a check on one district in which the northern and southern border lines were made to parallel the lines of latitude showed that the complexion of the results was not materially changed.

The mean variation of temperature with altitude for the entire United States for all years of record for 3,119 Weather Bureau stations, is shown in figure 2. The slope of this curve indicates a decrease in average temperature of approximately one degree for every 330-foot increase in altitude. This curve of temperature with altitude is not a straight line and the increment of elevation per degree of average temperature will vary. In a report from the United States Weather Bureau,[2] it is stated that the

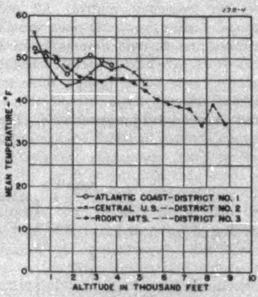

Figure 4. Variation of mean temperature with altitude for the northern districts of the United States

average decrease in temperature with increase in altitude in free air is about one degree for each 330 feet, but the rate varies with the season of the year and also is much affected by local conditions. It is more rapid in summer than in winter and is greatest during the warmer hours of the day. A study made of temperature variation with altitude made in England,[3,4] determined by sounding balloons, showed a decrease in temperature of one degree Fahrenheit for every 300-foot increase in altitude up to approximately seven miles, beyond which there is no further reduction in temperature.

The length of time records have been kept at the individual observation stations varies from 2 to 159 years. Through the use of mean temperatures for varying lengths of time the influence of periodic changes of temperature may be introduced. A method of extending short-term records has been suggested for the purpose of developing a satisfactory comparison between prevailing temperatures of two stations.[4] This may be done by comparing the mean temperature at the short-term station with the mean for a similar period of a similarly located long-term station and assuming that the same relationship would exist between the long-term means of the two stations. This procedure was not followed out in this paper, because it would multiply the analytical work tremendously and the increase of accuracy that might be expected would not warrant it. This is demonstrated in figure 3, which shows two curves of variation of temperature with altitude. One is the mean temperature for the year 1938 and the other is the mean temperature of all years of record. The year 1938 was a warm year and the annual mean temperatures for the entire country were above normal. However, in comparing the mean temperatures of one year with the mean temperatures for all years of record, it is seen that the curves are similar in shape and the difference between them is not great.

Figure 4 shows the variation of mean temperature for all years of record for the three northern districts numbers 1, 2, and 3, of the United States, and in figure 5 the same curves for the three southern districts numbers 4, 5, and 6 are shown. In order to interpret these clearly a brief description of how the data were worked up will be helpful. The mean temperatures for all years of record for all Weather Bureau stations were first calculated from the annual mean of 1938 and the deviation of this mean from the mean of all years of record.[1] It was then arbitrarily decided that the temperature data would be analyzed on the basis of 500-foot increments in change of altitude. The mean temperature of all stations located at altitudes between 0 and 500 feet, 501 and 1,000 feet, etc., were averaged and plotted halfway between the 0 and 500, 501 and 1,000, etc., ordinates on the curves. Analysis of the districts, using smaller increments for altitude, may influence the shape of the curve slightly, but will not seriously affect the general considerations involved.

Referring to figure 4, it is seen that the temperature decreases quite rapidly from 0–2,000 feet. There is then a reversal in the slope of the curve and the temperature increases gradually up to 3,000 or 3,500 feet. The mean temperature again falls off with increased altitude, but at a slower rate than in the first part of the curve. The curve of the Northern Rocky Mountain district seems to become erratic at the high altitudes. This is probably explained by the fact that there is only one Weather Bureau station in the ranges of altitude of 7,500–8,000 and 8,000–8,500 and only two in the range of 8,500 to 9,000. In ranges where only one or two stations are located unusual local conditions are not averaged out This is shown even more clearly in figure 5 in the curve for South Central United States for the ranges of altitude of 4,000–4,500 feet and 6,500–7,000 feet. These points are also for only one Weather Bureau station. The data for the point in the 4,000–4,500 range were taken at Alpine, Texas, and extend over a period of 16 years. Therefore, any extreme annual

Methods of System Control in a Large Interconnection

EARLE WILD
MEMBER AIEE

Synopsis: This paper describes the principles used in controlling the load in a large interconnected system. Automatic frequency controllers with time-error correction and tie-line controllers with frequency bias and time-error correction have been developed for co-ordinating the operations of interconnected systems of any size and geographical extent. Automatic control of two or more stations simultaneously within a group is described, and the relation of the auxiliary frequency controllers to the speed governors is also discussed.

Introduction

THE interconnection of many contiguous power systems into large co-ordinated groups of several million kilowatts has made imperative the development of control apparatus of great variety and refinement. The intended purpose of these interconnections required that economies of generation be maintained and that designated power flows be held steady. The geographical extent and the variety of relationships between the many properties made it necessary to use control equipment which would function in widely separated locations and with a minimum of direction. Increases in the size and number of large variable loads indicated the need for closer speed control. The final object of the control apparatus, therefore, was to maintain the most constant frequency and thus permit each local group to operate its individual system as local requirements dictate for maximum economy.

Basic System of Control

The original system of control consisted in giving one central group responsibility for the frequency control. All other groups starting from this point were interconnected through one or more tie lines which were held at definite scheduled loads. These other groups thus were varying their own generation locally, to meet their own load requirements. Theoretically, the frequency-control stations would only be following the variations in the load of the central group. Automatic frequency controllers and automatic tie-line controllers were used for this purpose.

Two objections arose to this simple plan. When two, three, or sometimes more of the tie lines departed from schedule in the same direction, the frequency-control station was unable to restore the frequency without an excessive load change. The other objection came from the continual variations in frequency causing the tie-line loads to vary. It was not only difficult to maintain these tie-line loads at scheduled value, but a large part of the regulation was being done in opposition to the frequency correction of the central group. Thus the original simple system of control did not function as well as intended.

Tie Line Biased by Frequency

These difficulties led to the development of the tie-line biased-by-frequency method of automatic control, which is

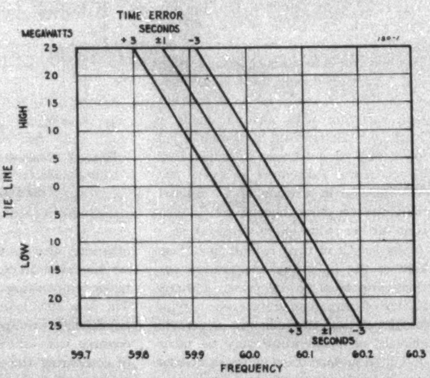

Figure 1. Characteristic curves of a tie-line controller

---

condition should be fairly well averaged out. The displacement can only be explained by unusual local conditions. On the other hand, the point in the 6,500–7,000-foot range is for the Weather Bureau Station at Mount Locke, where the period of record is only four years. Here a year of unusual temperature conditions might have affected the mean temperature some but probably not sufficiently to bring this point within the more or less expected trend of the curve.

Examination of figure 5 shows changes in slope at different points along the three curves, but these do not appear in the same range of altitudes as was the case with the three northern districts. As would be expected, the mean temperatures at the lower altitudes are higher than for similar altitudes in the northern districts. However, the curves for the northern and southern districts approach each other at the higher altitudes.

As seen from figure 2 the retardation and inversion of the temperature-lapse rate supports the general practice of making no correction for ratings for altitudes up to 3,300 feet (1,000 meters). Data are presented here from which a basic study may be made to determine the limits at which standard apparatus may be used at higher altitudes.

being used extensively in large interconnections. With it, the fundamental plan of regional control of loads is continued, but instead of holding tie-line loads at constant value, they are permitted to deviate from schedule whenever the frequency varies and in a direction to relieve the burden of the frequency-controlling center. The amount the tie-line load is varied, commonly known as *bias*, is a function of the frequency effect on load and the action of the speed governors of the turbines. This relationship will be described in a later section.

This bias principle permits tie-line loads to be varied in a relieving direction and be restored with a minimum change in generation in each group. It also assures the frequency-regulating center that several tie lines will be biased correctly for each one causing a frequency departure from normal. Thus any number of groups may be interconnected under this plan without increasing the burden of the central group.

The performance on several of these tie lines has been checked by means of counters, which register the deviations from normal. These show that most groups hold to scheduled tie-line loads about 70 per cent of the time, cause frequency deviations about 10 per cent of the time, and vary in a direction to relieve the frequency deviations 20 per cent of the time. Actually, each group on bias is assisting, in direction at least, twice as much as it is contributing to frequency deviations.

Frequency Effect on Load

Before the correct amount of bias could be determined for any system it was necessary to know the effect of frequency changes on the load. Studies were made in the Chicago system to determine the amount of load change for a given frequency change. It was found, as a very general rule, that one-tenth-cycle frequency departure resulted in approximately a one per cent change in system load. This figure is somewhat less than has been observed on some large interconnections, but has been checked many times since the staged tests were made, whenever important intersystem tie lines opened automatically under heavy load and there were sudden frequency changes. This figure takes into account the average response of a composite group of governors on the turbines affected, as they are found in normal service and without unusual attention being given to increasing their sensitivity or to block them.

This figure also includes some effect of voltage changes. Whenever the frequency departs from normal there is a change in voltage, due to change in the speed of the shaft-driven exciters on the main turbines. A test in one large load zone, which is mostly industrial in character, shows that whenever the voltage drops one per cent there is a $1^1/_2$ per cent drop in customer load. However, when the frequency drops there is not a general drop in voltage proportional to the drop in speed, as the automatic voltage regulators provide correction for at least 50 per cent of the load. Probably the largest effect of minor frequency changes comes both from a change in speed in the industrial motor load and the action of the more sensitive speed governors.

Tie-Line Bias Setting

The tie-line bias setting used is the one which will permit the tie-line load to change an amount equal to the group-load change for any given frequency deviation. As the frequency rises the load increases, but the generation remains constant except for the small decrease caused by the speed governors. The tie line supplies the difference and thus tends to oppose the frequency rise. When the frequency is restored to normal the tie-line load is returned to schedule without adjusting the generation. Thus whenever the frequency varies one-tenth cycle, the tie-line load is changed an amount equal to one per cent of the total generated load. This bias is extended proportionally for other departures from the normal of 60 cycles.

Time-Error Bias

There are times, however, after the frequency has departed from normal for a considerable period, when it is necessary to arbitrarily offset the frequency in the opposite direction in order to correct an integrated frequency or time error. If a great many of the tie lines in an interconnection are being operated on the tie-line bias principle, it becomes very difficult for the centrally-located frequency-control station to offset the frequency manually. It was desirable, therefore, to add time-error bias to each of the frequency-biased tie lines. Whenever the time departs from normal a time-error indicator, therefore, similarly causes a departure in tie line in such a direction as to offset the frequency and correct the time error.

Figure 1 is a chart of the relation of tie-line load to frequency and electric time error in a controller. All three of these factors must be satisfied, or the controller will change the system load until the tie-line load reaches a balance point. Figure 2 shows the changes in tie-line load as the frequency and time-error deviate from normal on a large group.

Description of Controllers

The equipment used in the control consists of the following apparatus:

1. Frequency controller with an electric time-error correction.
2. Tie-line controller.
3. Tie-line controller biased by frequency.
4. Tie-line controller biased by frequency and with electric time-error correction.
5. Cascading settings of tie-line controllers when used in series.
6. Devices for controlling the load on two turbines in separate stations.

The tie-line controller biased by frequency and with electric time-error correction, and the frequency controller with electric time-error correction will be described. Figure 3 shows a diagram of the electrical circuit of a typical tie-line controller, which has both frequency bias and time-error correction. The apparatus, as commonly used for this purpose, consists of a frequency bridge which is tuned for 60 cycles. One corner of the bridge has been opened and extended to a slide wire mounted in the recording tie-line meter. The zero or center point of this slide wire has a front "setter" and is placed at the scheduled tie-line point, wherever that may be from hour to hour. The movable contact of this slide wire is operated by the tie-line recorder carriage. Whenever the tie line is at the scheduled point, the contact is in the center of the slide wire and the frequency bridge remains balanced. If the tie line is displaced to one side or the other of the zero point, more resistance is inserted in one leg of the frequency bridge than the other, calling for a change in frequency in order to restore the balance of the galvanometer circuit or the correction of the tie-line load. Similarly, a second corner of the frequency bridge has been opened and extended to a slide wire in a time-error indicator. This time-error indicator consists of two electric motors, one driven by the system frequency and the other driven by the exact frequency of 60 cycles obtained from a crystal oscillator time standard. The speed of these two motors is compared through differential gearing, and any resulting displacement operates the pointer on the slide wire of the time-error indicator to change appropriately the balance point on the frequency bridge.

In order to regulate a system within plus or minus one second over widely scattered controllers requires that highly accurate time standards be provided. Some of the larger cities have sources of astronomical time, but these are not generally available over a wide interconnection. It has been agreed, in this interconnection, to use the primary frequency standard of the crystal oscillator type as a source of true time. These have an error of one part in two million and may be readily compared with observatory time as received from Arlington. Even assuming an error in setting these oscillators at widely scattered points, it will not be difficult to keep the time-error indicators within a quarter of a second of each other. The amount of tie-line departure that might be introduced by an error of a quarter of a second in the time standard would, at the most, be only one or two megawatts in any group.

The apparatus in the frequency-controlling centers is similar to the tie-line controlling apparatus described above, except that there is no tie-line slide wire. The bridge is continuously tuned for 60 cycles, except when the time-error indicator is displaced from its center point.

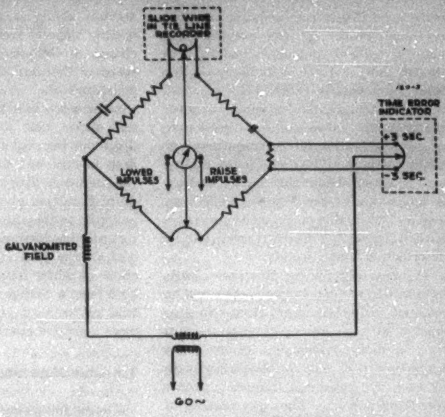

Figure 3. Circuit diagram of a tie-line controller, with frequency bias and time-error correction

The galvanometer is a Leeds and Northrup contact-making type, in which there are wiping cams which make contact with the "raise" or "lower" circuits once every two seconds. The duration of these contacts is proportional to the amount the frequency has deviated from the calibration value of the frequency bridge.

Rate of Load Response

The galvanometer circuit is unbalanced any time one of the three characteristics is varied from the normal value. If two of the characteristics are abnormal, the galvanometer is still further unbalanced unless these two are in opposition.

Comparison of these counterinfluences in the frequency bridge is very important. For example, if the tie line is off schedule and the frequency has not departed from normal, indicating that the load in some other group of companies is off schedule in the opposite direction, the controller sends out very short corrective impulses and it takes considerable time for this tie-line error to be corrected. Similarly, the other zone, whose generation is displaced from the correct value in the opposite direction, would be making a very slow correction and the load of the frequency-controlling center would not need to be disturbed. If, on the other hand, were the tie line to be off schedule in the same direction as the frequency, indicating that this group of companies is producing the frequency departure, the controller would send out very long impulses and cause the generation to change very rapidly at the point which was most responsible for the frequency departure.

The unbalancing of the bridge by time error is a much more gradual influence and requires, likewise, a much longer period for the time correction.

The controllers in the large group have been set to give a maximum correction to tie-line load of 20 megawatts in 30 seconds. The frequency-controller group has about one-half this rate of response, and the smaller groups are decreased to one megawatt a minute.

Cascading of Controllers

Several controllers may be installed in series along an extended transmission link, as shown in figure 4. The one most remote from the frequency-control center is given a bias setting proportional to the

size of its system. The next controller toward the frequency-controlling center is given a setting which includes its own proportional bias and the bias of the controller in back of it. If there are controllers in smaller companies which are on flat tie-line settings or which are held manually at a constant value, these, of course, are not taken into account in determining the bias setting. The controller which is nearest to the frequency-controlling center and having the highest bias may actually be operating in one of the smaller companies or one of the smaller generating stations. If the controller in the more remote company should fail to effect its tie-line departure, the controller more centrally located would then be called on for a contribution out of proportion to the size of the latter company. This is prevented in two ways: (1) By a suitable load-limiting band on the generators which restrict the departure to a proper value, and (2) by limiting the rate of response of the smaller controller so that the larger company will have sufficient time in which to make its correction before the smaller company has made an extended departure from its normal generation.

In one large interconnected system there are now 60 companies operating in parallel. These have generally adopted this principle of frequency and tie-line control. There are 17 of these controllers operating in parallel, 2 of them regulating the frequency only, and the other 15 on one or another form of tie-line control. The smaller companies are generally on flat tie-line control unless they are in series with a larger group which is on bias. One has installed time-error correction, and several others are now providing time-error correction equipment. With this method of control all local problems of generation are handled locally. Responsibility for frequency departures or inadequate generation is indicated at its source and corrected. The physical distance between companies or groups of companies is not a limitation, and new groups may be added to the interconnection and perform satisfactorily by adding a new controller without requiring changes in any of the existing facilities.

New interchange contracts which are made locally between any groups of companies do not call for changes in the apparatus, as it is adaptable to almost any power-flow requirements. The only precaution necessary is that the frequency bridges must be reasonably accurately tuned for 60 cycles. Where time standards are provided this is very simply checked, and where there are no standards, other apparatus, such as tuning forks, can be used, which will permit checking the frequency bridge accurately enough for load-control purposes.

Simultaneous Automatic Control of Two Stations

Once a company or group of companies have installed a controller, the problem arises as to the method to be used in utilizing the controlling impulses. The load and the number of generating stations have frequently grown to a point where it is not practical to assign the regulating responsibility to one station. This has been overcome in the Chicago area by the installation of one controller, which is sending its correcting impulses to two generating stations simultaneously. This appears to be the best arrangement in any company or group of companies which are operating under a pooling arrangement, and the control of the load on the local transmission system is not necessary.

After the controlling impulses are directed to two stations, it is desirable that the turbine selected for the automatic control in each station respond in similar amounts to the identical impulses. These turbines may be of different size and have entirely different governor characteristics. Two devices have been used for introducing these impulses into the governors of the respective turbines. One of these consists of a rheostat which operates a torque motor attached to the pilot cylinder of the governor, and makes a small and controlled load change. The two rheostats may be easily timed to travel at the same rate in the two stations, and by control of the necessary torque they can be made to make similar load changes, except at valve-opening points. These valve-opening points are traversed manually. This device, acting on the pilot valve, is not only faster in response than the synchronizing motor, but it avoids any inertia or loose play which is present in governor linkage. The rheostat also acts as its own load-limiting device.

The other apparatus which has been developed consists of an instantaneous wattmeter of the Kelvin balance or electronic type, in which the small driving motor in the meter is used to drive the carriage of the meter from the impulses of the controller. The impulses are also sent to the synchronizing motor, and if the turbine makes a larger load change than required for the length of impulses being used, the wattmeter becomes unbalanced and interrupts any subsequent impulses

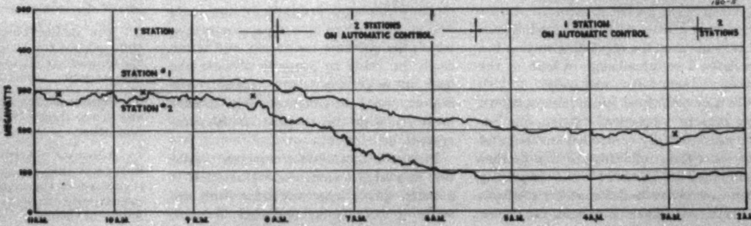

Figure 5. Load curves of two stations equipped for simultaneous automatic control

Amount of load variations at (X) increases sharply when only one station is on automatic regulation

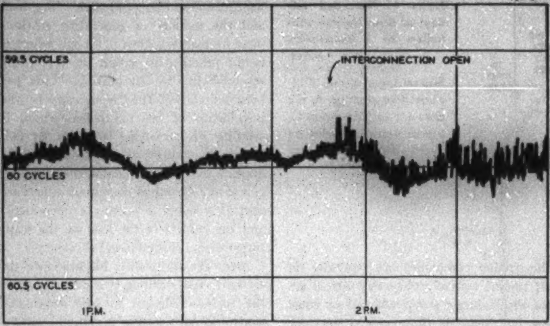

Figure 6. Frequency curve of a large system, showing effect of interconnections on width of frequency variations

to the turbine. The speed of the driving motors in the two wattmeters can similarly be timed together.

Need for More Automatic Control of Stations

In any station which has automatic load control, the variation in its load can be analyzed to come from two sources: One, the variations in the load of the system as it changes from minute to minute, and the other the irregularities in generation of the nonautomatic stations. These latter variations are caused largely by the inability of these stations to follow adequately the system-load changes. Frequently it has been found that some of the largest burden on the automatically-controlled station comes from the simultaneous delayed action on two or three other stations within the same group.

In the Chicago system an attempt was made many years ago to assist all stations in following the load trend by having a system totalizer in every operating gallery, which would indicate the total system load at all times. Each operator was then given a schedule which indicated the portion of the system total load assigned to that station. Although this method has proved quite workable, no operator is able to follow manually the trend as fast as the automatic station does, and so after each large load change it is found that the regulating station has to make a counterchange of load as the other stations follow manually.

In a system of, let us say, five stations, one may be a base-load station, another the automatically-controlled station, and the other three following the trend either manually, as observed on a totalizing meter, or under load dispatcher's orders. If these latter three, or at least the one or two of them making the largest load variations, could make their change in load before the full-load change of the automatic station has been completed, the burden on the automatic station would be very sharply reduced.

The experience in Chicago with two stations operating simultaneously (figure 5) indicates that the burden on either one is less than half what it would be if only one were on automatic control. This indication has proved so definite that steps are now being taken to extend the automatic control to practically all the major generating stations. The so-called base-load stations during the minimum hours become the variable-load stations on the system, and at these hours take over the automatic regulation.

Relation of Controllers to Governors

The function of the auxiliary speed device or frequency controller, as it is commonly called, does not supersede that of the speed governor. The speed governor must continue to maintain instantaneous frequency, but in maintaining this frequency it distributes the load in a manner that is often not desired. The controller, on the other hand, is relatively slow in its action, but it does give droop correction, which the governor cannot do, and it can easily be made to properly allocate the load in any proportions desired. The importance of the governor seems to vary inversely with the size of the electrical system.

Figure 6 shows the frequency variation in a large system while it was part of a much larger interconnection and also while it was being operated isolated. Certainly it is apparent that the smaller systems, especially if supplying variable loads, must have the turbines equipped with the best governors available. In the large interconnections, on the other hand, there is an enormous inertia effect available, which holds the system speed within a very narrow band. This has led to the belief in some quarters that the governors should not be too sensitive and may even have a small dead band.

The load-control problem is generally rather easily handled in a small isolated system. The large interconnection-load control is much more difficult. Although the instantaneous frequency varies but little from minute to minute, it does drift over the longer period of hours or more, over a much wider band than is found in the small systems. This is a load-control problem, which must be handled by the controllers or by supplementary manual action.

The manufacturers have proposed that governors be built with a sensitivity of 0.04 per cent and a per cent regulation up to two per cent. These are undoubtedly desirable on the smaller systems, but on the large interconnections governors with a sensitivity of 0.08 per cent and from four per cent to six per cent regulation would be satisfactory. Where flat tie-line regulation is used, the action of too responsive governors is contrary to the action called for by the controllers. With the tie-line bias principle, however, more responsive governor action could easily be accommodated by increasing the amount of bias setting. The problem of modernizing enough governors in a large interconnection, where they may run up to 1,000 in number, so that a few will not be carrying a large portion of the regulation, is very difficult, and also the benefits to be derived from such a program are probably quite limited.

Conclusions

1. A centrally located frequency control with automatic tie-line controllers maintaining the proper loads locally, has proved to be a practical method of holding steady the frequency in large interconnections, regardless of size or numbers of interconnections.

2. The tie-line biased-by-frequency principle relieves the regulating burden on both the frequency control and the tie-line regulation stations.

3. Several of the variable-load stations in any group should be sharing the automatic regulation.

4. Adequate governors are necessary, but it appears that the sensitivity and per cent regulation of these governors may vary inversely with the size of the systems and the nature of the load.

Modern Relaying for A-C Secondary Network Systems

D. L. BEEMAN
ASSOCIATE AIEE

Synopsis: This paper outlines the application of a new three-phase, single-element induction cylinder network master relay which uses line-to-line connected potential coils. Previous network master relays were three-phase, three-element and employed line-to-neutral connected potential coils.

The new relay with line-to-line connected potential coils produces far greater tripping torque during unbalanced primary feeder faults than the older relays with line-to-neutral connected potential coils. Examples are given to show the advantage of the new relay.

Modern relays have materially improved tripping characteristics which extend the range of highly leading and lagging currents over which the relays will operate selectively at normal balanced three-phase voltages.

The mechanical improvements of the network relays are discussed.

Introduction

DURING the past decade there have been many improvements in relays for a-c secondary network systems. There have been no basic changes in the functions performed by these relays. However, the introduction of a new single-element, three-phase induction cylinder relay with line-to-line connected potential coils and improved electrical and mechanical features, represents a basic change in the design and performance of these relays. The major improvements have been made in tripping performance and mechanical construction.

In the conventional *a-c secondary network system,*[1] figure 1, a secondary grid is fed by a number of network transformers which are supplied from a substation through two or more high-voltage feeders. The function of the network protector, located on the secondary of each transformer, is to disconnect automatically all transformers, on a faulty feeder, from the secondary grid. Hence, the grid will remain energized and continue to supply all loads from the healthy primary feeders. After the faulty feeder has been restored to normal and re-energized, it is the second function of the network protector to automatically reconnect the transformers on that feeder to the secondary grid.

The tripping of the network protectors is performed by a three-phase power directional relay, commonly called the "master relay," and the reclosing is performed by the same three-phase relay in conjunction with a single-phase "phasing relay."

Secondary network systems are now being more generally applied to areas which are relatively *lightly loaded.*[2] Installations in these areas are characterized by wide spacing of transformers, and relatively high secondary grid impedance, and consequently *lower fault voltages and currents* during primary feeder faults than are generally encountered in heavy-density systems which are more closely coupled. Hence, it is more difficult for the master relay to operate to trip the network protector during primary feeder faults in light-density than in heavy-density secondary network systems.

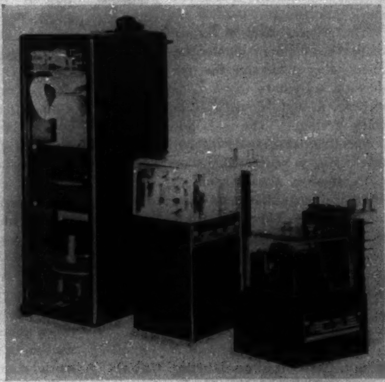

Figure 2. Three types of three-phase network master relays

Left—Three-element induction disk relay

Center—Three-element induction cylinder relay

Right—Single-element induction cylinder relay

New Single-Element Master Relay

The new single-element three-phase master relay, figure 2 (right) overcomes this difficulty first because on three-phase primary feeder faults it produces more torque in proportion to the weight of the moving element than does any other master relay. Hence, there is a greater margin between the total torque and the friction torque which increases the useful torque available for operating the relay.

given relay will produce considerably *greater torque under unbalanced primary feeder fault* conditions with *L-L* than with *L-N* connected potential coils. The torque produced during three-phase primary feeder faults or under balanced three-phase conditions is the same for a given relay whether *L-L* or *L-N* potential coil connections are used.

The greater ratio of torque to weight of moving element makes the single-element relay attractive for use in heavy-density secondary network systems as well as in light-density secondary network systems. The *L-L* potential coil connections are advantageous for master relays used in heavy-density networks because there is always some reduction in voltage when unbalanced primary feeder faults occur. Therefore, the new single-element master relay, although originally developed for light-density network systems, is now applied to heavy-duty network protectors for heavy-density networks. The following discussion applies to network systems in general.

Relay Performance During Unbalanced Primary Feeder Faults

The advantage of the three-phase single-element relay with *L-L* connected potential coils can be readily seen by referring to figure 3 and table I. In table I comparisons are made at three different voltages. Figure 3 is a vector diagram of the voltages existing at the relay for *a line-to-ground primary feeder fault on a wye-connected transformer*. There is fault current I_1 in only one phase of the system, and hence only one phase of the master relay. With the older relays, with *L-N* connected potential coils, this current I_1 reacts with line-to-neutral voltage e_1 which is very small and the power factor is very low. With the new three-phase single-element relay with *L-L* connected potential coils, the torque is considerably greater because the same fault current I_1 reacts with line-to-line voltage E_{3-1} which is far greater in proportion to normal than e_1. Furthermore, the fault current is closer to the maximum torque position of the *L-L* relay, which further increases its torque.

Other possible unbalanced primary feeder faults are: (1) double line-to-ground, and (2) line-to-line faults. The actual torques for two similar relays with *L-N* and *L-L* connected potential coils are compared in table II.

The vector diagrams in figures 4, 5, and 6 show pictorially the relation between the fault voltages and currents in the two relays employing *L-L* or *L-N* potential connections.

The increased torque of the new relay during unbalanced primary feeder faults provides more positive operation and also increases the speed of operation of the relays, table III.

Hence, it permits more latitude in selection of network-protector fuses without the probability of a fuse blowing on unbalanced primary feeder faults before the master relay trips the network protector.

The greater torque of this relay has proved particularly advantageous where higher reverse power settings are required to prevent "pumping" of the network protector during normal operation. These higher settings may actually prevent a relay with *L-N* potential coils from tripping during certain unbalanced primary feeder faults. The greater torque produced by the single-element relay with *L-L* connected potential coils permits greater reverse power settings without the relay failing to trip on unbalanced primary feeder faults.[3]

Singe-Phase Switching of Primary Feeders

In some installations light-density networks are fed from overhead 4-kv wye-connected primary feeders with *single-phase switching* at the source or single-phase fuses between the source and the network transformers. A single phase-to-ground primary feeder fault may open only the faulty phase at the substation or at the fuse. Then there is reverse power on one phase being fed from the secondary grid through the transformer. This produces a tripping torque on one phase of the master relay. The other two phases may be supplying load to the network grid and this would produce a nontripping torque in the other two phases of the master relay. If the relay is to trip the protector the torque produced by the fault current and voltage in one phase must overcome the torque produced

Table I. Comparison of Relays for Line-to-Ground Fault, Figure 3

Fault Current (I_1)* (Per Cent)	Potential Coil Voltage Which Operates With (I_1)*	Angle Between Fault Current and Maximum Torque Angle of Relay (Degrees)	Per Cent of Normal Torque**		Ratio of Relay Torque L-L to L-N
			L-L Relay	L-N Relay	
200	10% e_1	75		1.7	15.30
200	58% E_{3-1}	47	26		
500	25% e_1	75		11	6.1
500	71% E_{3-1}	55	67		
1,400	70% e_1	75		81	1.70
1,400	85% E_{3-1}	51	139		

*Fault current and potential coil voltage are in per cent of rated current and voltage of associated network transformer.

**Normal torque is the torque produced by the relay with all three phases energized with rated voltage and rated current at the angle of maximum torque.

Table II. Comparison of Master Relays for Various Types of Unbalanced Primary Feeder Faults, Figures 4, 5, and 6

Basis: Fault Voltage Equals 25 Per Cent of Normal. Power Factor of Fault Current 75 Degrees Lagging

Type of Fault	Transformer Primary Connection	Per Cent of Normal Torque		Ratio of L-L to L-N Relay Torques
		L-L Relay	L-N Relay	
Double line-to-ground	Wye	$15.1\frac{I^*}{I_n}$	$4.2\frac{I}{I_n}$	3.6
Line-to-line	Wye	$24.8\frac{I}{I_n}$	$3.7\frac{I}{I_n}$	6.7
Line-to-line	Delta	$21.4\frac{I}{I_n}$	$3.2\frac{I}{I_n}$	6.7

* $\frac{I}{I_n}$ = Ratio fault current to rated current of network relay.

Table III. Comparative Operating Times of Similar Relays on Single Phase-to-Ground Primary Feeder Faults, Figure 3, With L-L and L-N Connected Potential Coils

Fault Voltage 25 Per Cent Normal and Power Factor of Fault Current 75 Degrees

Fault Current In Per Cent of Normal	Operating Time in Seconds	
	L-L Relay	L-N Relay
500	0.16	0.9

by the load current in the other two phases. The increased tripping torque of the single-element relay with *L-L* potential coil connections will be beneficial in these cases. Single-phase switching on primary feeders to secondary networks *is to be avoided wherever possible.*

Relay Connection

The basic differences in *L-L* and *L-N* potential coil connections are shown in figure 7. In this figure the *L-L* connections are shown to involve three potentials for the sake of simplicity. The actual connections of the new three-phase single-element master relay[4] are shown in figure 8. This relay uses two sets of potential coils in open delta.

Improved Tripping Characteristics

In addition to tripping on primary feeder faults as outlined above, network master relays must trip on very low values of reverse power flow (i.e., power flow from the grid to the network) such as transformer-core loss and cable-charging current, to enable clearing a primary feeder by merely opening the station breaker.

Since the relay must function on *very small power reversals* involving very highly leading cable charging current I_c and lagging transformer exciting current I_m, the ideal tripping characteristic would be that of a true wattmeter or curve *a-a'*, figure 9.

Practically, it is not possible to build a relay which has a truly wattmeteric characteristic because of the saturation of the iron used in the magnetic structures of the relay and the current transformers. The effect of saturation is to produce a characteristic like that of *c-c'*, figure 9. Currents through the protector represented by vectors terminating to the left of the characteristic will cause the master relay to trip the protector. Current vectors terminating to the right will not cause the master relay to trip the protector.

Improvements in the *quality of iron* available and refinements of the design of the *magnetic structures* of the relay have resulted in tripping characteristic *b-b'* (figure 9) for the modern induction cylinder single-element and three-element, three-phase master relays as compared with characteristic *c-c'* for early types of induction disk master relays.

The newer induction cylinder master relays with straighter characteristics enable more universal application as they permit selective operation with larger highly leading and lagging currents. The characteristics of earlier induction disk master relays were so bent that it would

Three-phase single-element induction cylinder relay (new)	26	465	231	33

not be to the right of both I_c and I_m. Hence, it was necessary to adjust the characteristics of many of these relays to meet varying conditions and to restrict their application to locations where cable-charging currents were negligible.

Mechanical Improvements

The mechanical improvements of network relays can be seen in figure 2 and table IV where the principal characteristics were given.

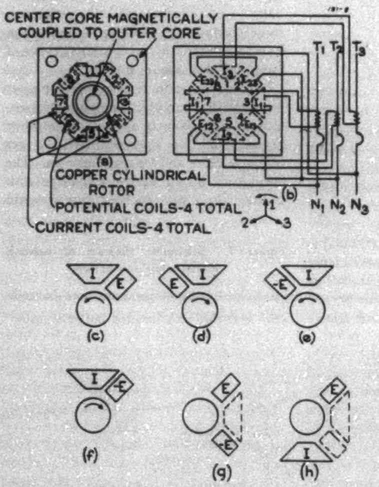

Figure 8. Schematic connections of single-element three-phase master relay

The induction disk master relays, figure 2 (left), were relatively inefficient and occupied considerable volume. To permit a reduction in the size of protectors, it was desirable to reduce the size of these relays. This and the desire to improve the relay performance led to the development of the three-phase three-element induction cylinder relay shown in figure 2 (center). Electrically, this relay was the same as the induction disk type, i.e., it had three independent single-phase elements all on a common shaft and had *L-N* connected potential coils. The new single-element relay is a further improvement of the induction cylinder design in that all three phases are combined in one element with only one rotor.

Network relay adjustments have been simplified in that individual phase adjustments are not required. *Drag magnets* which were a source of maintenance on the older relays have been eliminated. Contacts have been developed that will withstand several thousands of operations without maintenance.

The above-mentioned refinements have been made mainly to *reduce maintenance* and to enable *longer time between inspection periods.* Maintenance is a particularly important factor in network relays because they are mounted in inaccessible locations.

Network relays operate at extremely low torques when tripping on transformer exciting current. Hence, friction plays an important part in the performance of these relays. The single-element master relay has a much lighter moving element; hence, the *friction force is lower*, and consequently operation is more positive. Induction cylinder relays have balanced magnetic circuits and are inherently free from vertical vibration. Hence the major source of bearing wear has been eliminated.

Modern network relays operate at a *lower temperature rise*, i.e., about 40 degrees centigrade rise over ambient around relay, to allow for higher ambients encountered inside higher capacity submersible network protectors now being built, without unduly shortening the life of the relay coils.

Summary

A new three-phase, single-element induction cylinder relay has been introduced which, although functionally the same as previous relays in so far as network-protector control is concerned, has:

1. Line-to-line connected potential coils instead of line-to-neutral connected potential coils which provides a far greater tripping torque during unbalanced primary feeder faults.

2. This is particularly advantageous in light-density network systems where fault currents and voltages are lower than in heavy-density systems which are more closely coupled. The line-to-line connected potential coils offer advantages in heavy-density systems too.

Five Years' Experience With Ultrahigh-Speed Reclosing of High-Voltage Transmission Lines

PHILIP SPORN
FELLOW AIEE

C. A. MULLER
MEMBER AIEE

Synopsis: The data covering five years' operating experience with 33 ultrahigh-speed reclosing breaker installations mainly on a large interconnected and integrated high-tension system are presented and analyzed, and conclusions based on this experience are drawn. Out of 71 cases of flashover cited, 65 reclosures were successful and 6 cases of reclosure resulted in restrikes, a record of 91.5 per cent successful reclosures. The conclusions drawn are that not only is actual performance better than appeared possible when the development was first made but that further improvements are possible by further reducing breaker time.

I. Introduction

THE basic principles of ultrahigh-speed reclosing of high-voltage transmission lines have been previously presented[1] in a paper before the Institute. Likewise, operating experience with the original high-speed reclosing equipment first developed and with a modification of that equipment were presented[2] two years ago. However, the data available at that time covered only three sections (six terminals) of high-voltage transmission lines and a period of only three years, in one section of which the equipment was in service for only one year and another the equipment was in service for only a portion of one year, so that operating experience with only 15 cases of reclosure could be cited and discussed. Since then, however, the application of ultrarapid reclosure has not only been widely extended but a great many more operations have been experienced. These now constitute a set of data that is extensive enough to be able to furnish a basis for some well-founded conclusions. It is the purpose of this paper to present and analyze these data and draw such conclusions therefrom as are warranted and pertinent.

II. System on Which Installed

The system on which all terminal equipments with the exception of four (representing two line sections) have been installed is the central system of the American Gas and Electric Company. This is shown diagrammatically in figure 2. This system is an integrated system operating in seven states and comprising altogether 1,455 miles of 132-kv transmission, substantially all of which is of double-circuit steel-tower construction with a total, as of the date of writing, of 2,483 miles of circuit. It serves a load whose last-recorded maximum one-hour integrated peak was 997,000 kw. On this system the power supply, that is, power generation and power transmission to load centers, is integrated and co-ordinated to the highest degree. The system, which is a predominantly steam-electric system, nevertheless has a substantial portion of hydro capacity. Besides this, extensive and important foreign interconnections exist on several portions of the system through which diversity and other exchanges are carried out with adjacent systems. This, coupled with the diversities in load and, to some extent, of time over the system, makes imperative frequent and in many cases sudden changes in power flow over many of the important transmission lines on the system. Besides that, the availability of economical supplies of hydro in portions of the system and the concentration of generation by steam-electric stations at the points where combined optimum fuel and water conditions prevail, make economically desirable and necessary the transfer of heavy flows of power, at one time or another, over most of the transmission lines on the system. Under these conditions, the importance of continuity of supply, if the entire system is to operate in accordance with predetermined principles of economy, is apparent. Hence, the first and so far the widest application for ultrahigh-speed reclosing has been found on that system.

The four remaining terminals not installed on the central system are on the double-circuit Deepwater-Atlantic City lines of the South Jersey system. These two circuits are installed on 132,000-volt towers and insulated for that voltage but are operating at present at a voltage of 66 kv.

The first installation using the experimental equipment was on the Fort Wayne-Deer Creek circuit in Indiana. As will be noted from the diagram, since then 27 additional terminals (13 line sections) on the system have been installed covering a total circuit mileage of 655 miles. These have been extended progressively as the need for them arose and as the operating advantages or necessities were indicated.

III. Operating Experience

A summary of the total operating experience since the first installation is given in table I. Referring to that table it will be seen that taking the two systems which the record covers, a total of 33 terminals involving 16 line sections have been covered, and that these 16 line sections cover approximately 840 circuit miles of line, all but 126 of which operate at 132,000 volts. In the period May 1936 to November 1940, covering substantially five lightning years, 72 cases

Paper 41-52, recommended by the AIEE committees on power transmission and distribution and protective devices, and presented at the AIEE winter convention, Philadelphia, Pa., January 27–31, 1941. Manuscript submitted November 16, 1940; made available for preprinting December 12, 1940.

PHILIP SPORN is vice-president and chief engineer, and C. A. MULLER protection engineer, for the American Gas and Electric Service Corporation, New York, N. Y.

[1] For all numbered references, see list at end of paper.

---

3. The tripping characteristics have been improved to permit operation at normal voltage over a wider range of highly lagging and highly leading currents.

4. There have been many mechanical improvements in network relays which have improved their performance and reduced maintenance.

of flashover resulting in line opening occurred. Of these, 63 cases were single-line trouble and 9 cases were two-line trouble. Out of the same number of 72 cases of flashover, 65 reclosures were successful and 7 cases of reclosure resulted in restrikes. This is a record of 9.7 per cent unsuccessful reclosures; but in this connection it needs to be pointed out that in one of these cases permanent physical damage had previously resulted to a tower and that under such conditions obviously successful reclosure was a physical impossibility since nothing but a permanent outage could clear the trouble. Disregarding, therefore, this one case, the total unsuccessful reclosures were six, representing a percentage slightly over eight per cent. An interesting thing in this connection, too, is that in not a single case did the equipment fail mechanically, that is, the mechanical performance was in every case perfect and reclosure was carried through and was successful in every case where the circuit condition permitted re-energization of the line. Table I shows clearly, too, the rapid accumulation of experience with the year 1940. It will be noted that the percentage of restrikes or unsuccessful reclosures for 1940 was again slightly over eight per cent, the same figure as for the total five-year period.

The table further shows the distribution of faults between phase to ground, phase to phase and ground, and three phase. Of the 71 cases of flashover, 55 cases were phase-to-ground faults on one line with 53 successful reclosures and only two restrikes which were probably due to multiple lightning stroke as explained in previous paper.[3] Three cases of phase-to-phase and ground faults on one line occurred, all of which reclosed successfully. Five cases of three-phase faults on one line occurred with three successful reclosures and two restrikes. Three cases of phase-to-ground faults on two lines occurred, all of which reclosed successfully. Four cases of phase-to-phase and ground faults on two lines occurred with three successful reclosures and one restrike. One case of three-phase fault on two lines occurred which restruck.

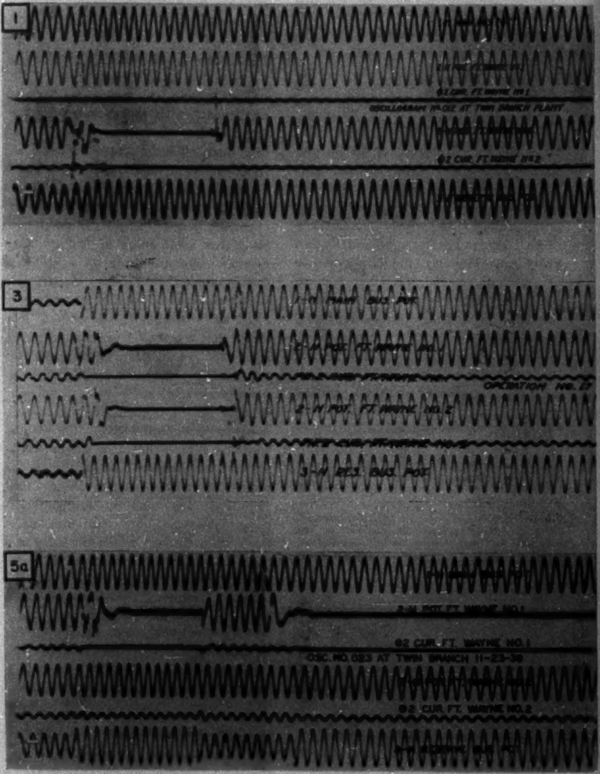
IV. Some Typical Oscillograms and Their Significance

In figure 1 are shown five sets of oscillographic records taken at Twin Branch station showing system performance for five typical cases of trouble on the system. The top and bottom traces on all oscillograms represent phase 1-to-neutral and phase 3-to-neutral voltages respectively on 132-kv bus at Twin Branch station. The second and fourth traces from the top indicate phase 2-to-neutral voltages of number 1 and number 2 Twin Branch-Fort Wayne lines respectively taken on the line side of the breakers at Twin Branch station. The third and fifth traces from the top represent phase 2 line currents on number 1 and number 2 Twin Branch-Fort Wayne lines respectively.

Oscillogram number 1 is a record of a lightning flashover on number 2 Twin Branch-Fort Wayne line involving phase 3 to ground that occurred at 9:34 p.m. on July 22, 1939. The fault was cleared in approximately $6^1/_2$ cycles and after a line de-energization of 12 cycles, reclosure was entirely successful.

Oscillogram number 2 is a record of a lightning flashover on number 1 Twin Branch-Fort Wayne line involving phase 1 to ground that occurred at 2:21 p.m. on June 18, 1940. The fault was cleared in approximately eight cycles and after a line de-energization of seven cycles, the line was re-energized from one end and three cycles later the breaker at the other end reclosed. The difference in reclosing times of the two breakers was due to the experimental adjustment of breaker-contact operating speed which existed at this time. With this adjustment the breaker contacts reached a point five-eighths inch from contact "make" position after 15 cycles and hesitated at this point, completing the stroke at 18 cycles. It is believed that when the five-eighths inch point was reached, the breaker at one end of the line arced across its contacts, thus energizing the line. As soon as the line was energized, most of the potential

Figure 1. Oscillograms of actual operation on the 132-kv transmission system of the central system

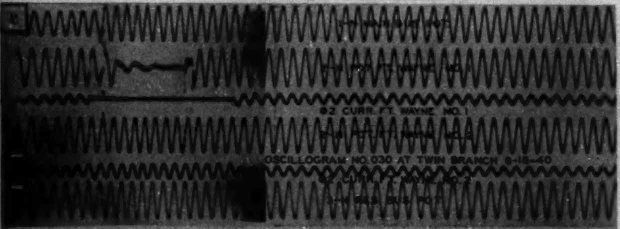


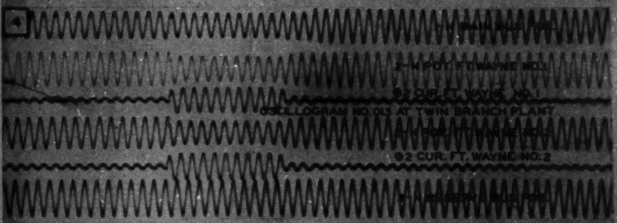
across the contacts of the breaker at the other end disappeared and the circuit was therefore not closed until electrical contact was finally made by the second breaker at 18 cycles.

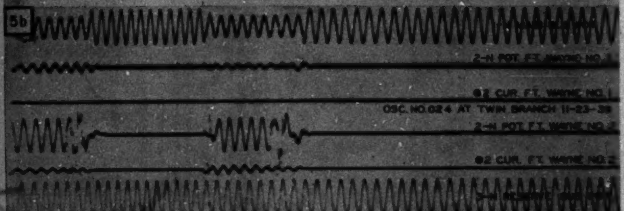
Oscillogram number 3 is a record of lightning flashover occurring simultaneously on number 1 and number 2 Twin Branch-Fort Wayne lines involving phases 1 and 3 to ground that occurred at 12:50 a.m. on July 8, 1939. Both lines were opened at both ends in approximately $6^1/_2$ cycles after the inception of the fault and after both lines had been de-energized for $11^1/_2$ cycles, reclosure of all four breakers on both lines was entirely successful.

Oscillogram number 4 is a record of lightning flashover occurring simultaneously on Fort Wayne-Deer Creek and Fort Wayne-Delaware lines involving phases 1 and 2 to ground that occurred at 12:13 a.m. on July 23, 1939. At this time the Fort Wayne-Deer Creek line only was equipped with ultrahigh-speed reclosing equipment, which line reclosed successfully. The Fort Wayne-Delaware line was only protected with instantaneous overcurrent relays in conjunction with time-delay overcurrent relays. Under these conditions, it is to be noted that both lines opened up at both ends $10^1/_2$ cycles after the inception of the fault.

Oscillogram number 5 is a record taken when mechanical damage occurred to a steel tower on number 1 and number 2 Twin Branch-Fort Wayne lines at 9:54 p.m. on November 23, 1939. From the oscillogram it will be noted that a fault involving phase 3 to ground occurred first on number 1 line, which opened at both ends $7^1/_2$ cycles after the inception of the fault and reclosed after de-energization of the line for ten cycles and reopened due to permanent trouble on the line section. Approximately 30 cycles later number 2 line became involved in the trouble with phase 1 going to ground, opening both ends after $6^1/_2$ cycles and reclosing after line had been de-energized 12 cycles when it retripped on account of permanent trouble on the line section.







V. Additional Installations

The accumulated operating experience has been so beneficial and the results obtained so much greater than even the authors originally anticipated that as the continuity problem and the problem of reliability of supply had to be met on other sections of the system, ultrarapid reclosure was extended and is still being extended today. Thus at the present time there are 12 additional terminals in process of installation covering additional 6 line sections with a total 224.2 miles of 132-kv circuit. These are clearly indicated in the diagram figure 2. Other points on the central system, and on the other two systems of the American Gas and Electric Company where the same general problem is being studied, are being seriously considered for equipment with ultrarapid reclosure on the terminal breakers and there is no doubt in the authors' minds that such additional applications will be found desirable and/or necessary. Particularly is attention being given to medium-voltage lines in the subtransmission or distribution class such as those of 23,000-volt and 33,000-volt rating. Here, however, the problem that still has to be solved is the one of providing an economical reclosing mechanism and a relay arrangement that will combine the basic elements of one cycle differential operation without the expense involved in the present system. While neither of these two problems has been entirely worked out the present indications are that both can and will be.

VI. Conclusions

Based upon the five years' experience studied and discussed here the authors believe that the following conclusions are clearly indicated:

1. In general on a high-voltage system properly insulated and provided with ground-wire protection at least 90 per cent successful reclosure can be expected by the use of ultrarapid reclosing. In the case of the two systems cited and discussed, out of 72 operations 71 were apparently due to lightning and of these 65 reclosures were successful. This is a record of better than 91 per cent successful operation and compares with the previously indicated figure of not less than 75 per cent successful operation.

An Improved Polyphase Directional Relay

BERT V. HOARD
MEMBER AIEE

THE inductor-loop principle of operation has been employed successfully for many years in building single-phase directional relays of the high-speed type. This principle of operation has now been extended to obtain a high-speed polyphase directional relay of a radically different type of construction than has been employed heretofore, which has such features as simplicity, compactness, low burden, high sensitivity, and nonbounce contacts.

The trend toward high-speed operation for all types of protective-relay applications has developed a need for such a relay. This is particularly true in directional-comparison schemes of pilot relaying. Other applications include the use of a polyphase directional element with instantaneous overcurrent or impedance relays and for these applications high speed in the directional element is needed for proper co-ordination.

The principle of operation of the inductor-loop element is that of a conductor carrying current in a magnetic field. The inherent efficiency and simplicity of the magnetic circuit combined with low inertia of the inductor loop makes possible a directional-relay design having a high torque-to-weight ratio which is essential if sensitive, high-speed operation is to be obtained.

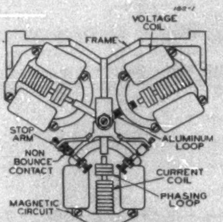

Figure 1. Diagram of electromagnets, loops, and contacts

The arrangement of the components of such a relay element designed for three-phase operation is shown schematically in figure 1. It consists of three electromagnets and three loops around a vertical shaft. Each loop is mounted on the shaft with its outer side located in an air gap within the electromagnet. The voltage coils, one on each of the outer two legs of each electromagnet, have a voltage applied which induces a large current in the loop by transformer action. Current flowing through the current coil, which is located on the center leg of the electromagnet, produces an air-gap flux which interacts with the loop current in the outer side of the loop and causes rotation of the shaft in a direction corresponding to the flow of alternating current power. If the direction of current flow reverses, the torque and the direction of rotation of the shaft reverse. A photograph of the relay is shown in figure 2.

The phase-angle characteristic of the inductor-loop electromagnet is essentially that of a watt element, although maximum torque is obtained when the applied current is slightly lagging the voltage. In the voltage circuit the loop can be considered as the secondary load of a transformer which has a high resistance compared to its reactance, so that the loop current lags the primary voltage by an angle of about 15 degrees. In the current circuit the air-gap flux is in phase with the applied current. When loop-current and air-gap flux are in phase, maximum torque is obtained, hence this condition is fulfilled when the applied current lags the voltage by 15 degrees.

One loop and its associated electromagnet make up one phase of the three-phase relay, and a delta voltage and a star current are applied. For actual installations, the 90-degree connection is normally used for polyphase directional relays because during phase-to-phase faults more sensitive operation will be obtained, since the two elements carrying fault current have the two unfaulted

Paper 41-62, recommended by the AIEE committee on protective devices, and presented at the AIEE winter convention, Philadelphia, Pa., January 27-31, 1941. Manuscript submitted November 18, 1940; made available for preprinting December 13, 1940.

Bert V. Hoard is relay development engineer for the Westinghouse Electric and Manufacturing Company, Newark, N. J.

---

2. The probability of restrike on double-circuit lines of the type existing on the central system in case of double-circuit flashovers is approximately four times as great as in the case of single-circuit flashovers. Thus, in the case of the two systems described, out of eight cases of two-line trouble (omitting the one due to permanent disability) two restrikes occurred or a restrike record of 25 per cent. On the balance of 63 cases of one-line flashover, four restrikes occurred or a restrike record of 6.5 per cent.

3. Ultrarapid reclosure has definitely established itself as an indispensable tool in high-tension integrated power systems. A definite start has been made in the direction of extending it to lower voltage lines. Further development here is needed and will depend upon the successful removal of the economic limitation to the extension of this application to such lower voltage and, therefore, lesser capacity lines.

4. There is reason to believe that the present 8.5 per cent unsuccessful operation can be reduced and particularly that the percentage of 25 per cent failure to reclose successfully on two-line faults can be reduced. The means for carrying this out so far indicated are as follows:

(*a*). Reducing the total percentage of two-line flashovers by further increasing the speed of clearing of the fault.

(*b*). Reducing the percentage of restrikes by speeding up the clearing time and thus permitting a corresponding increased waiting time before reclosure is attempted.

delta voltages applied to them, respectively. Using this connection, one of the electromagnets will have line current from phase *a* and the delta voltage opposite phase *a* applied. Thus, for unity power factor in the system, the current through the relay electromagnet is leading the applied voltage by 90 degrees, and for a fault which causes the system current to lag by 45 degrees the relay current leads the applied voltage by 45 degrees.

For the 90-degree connection the relay phase-angle characteristic should, therefore, be shifted so that maximum torque is obtained when the relay current leads the relay voltage by 45 degrees. A series resistance-phase shifter, similar to that commonly used in the induction-disk type relay cannot be used for the inductor-loop relay, because the latter has a voltage circuit which is mostly resistance. However, a series capacitor of the proper size will produce the 45-degree phase-angle characteristic as shown in the diagram of figure 3*a*.

A simpler phase shifter and one that is better from an operating and maintenance standpoint is the use of a phasing loop on the magnetic circuit in front of the current coil as shown in figure 1. The phasing loop consists of three heavy rectangular-shaped copper washers and causes the air-gap flux to lag behind the applied relay current, so that the current must be advanced in phase position to bring the loop-current and air-gap flux back in phase and obtain maximum torque. This type of phase shifter is used on the relay to obtain a 45-degree characteristic as shown in figure 3*b*. To obtain the same magnitude of air-gap flux and relay sensitivity, a larger number of turns are used on the current coil when phasing loops are used. Even with the increased number of turns required, the burden of the current circuit is very low as shown subsequently.

The instantaneous torque in any one electromagnet of the relay is produced by the instantaneous products of voltage (loop current) and current (air-gap flux) in the electromagnet, which is a double-frequency pulsating torque. Figures 4*a* and 4*b* show this torque respectively for phase angles when the average torque is a maximum and when it is zero. The torques in the other two electromagnets are also pulsating as shown, respectively, in figures 4*c* and 4*d*; however, they are displaced 120 degrees in time phase from each other and when all three instantaneous values are added up, the result is a uniform nonpulsating torque. Hence, under normal conditions with the three applied currents and voltage balanced there is no tendency for these torques to cause vibration. During unbalanced faults, in general, there will be a combination of a balanced torque and a pulsating torque on the moving element and the pulsating torque will tend to produce some vibration. However, this vibration has been minimized through proper moving element and contact design which keeps the contacts positively closed when the unbalanced torque is present.

The contact travel for any type of high-speed relay is necessarily small as one means of obtaining high speed. For this relay, due to its extremely high ratio of torque to inertia, the normal travel of 0.030 inch is greater than has been customarily used in the past for similar relays. Nonbounce contacts are used, which consist of a small enclosed cylinder partially filled with tungsten powder mounted on the end of a flexible spring. When the cylinder strikes the rigid stationary contacts, the particles of tungsten slide over each other and absorb the energy of impact. After the contact spring has been slightly deflected, the adjusting screw in the stop arm (figure 1) strikes the moving contact cylinder and then the full torque of the relay is transmitted to the moving and fixed contacts. Hence, the contacts act as the moving-element stop and full contact pressure is assured at all times. Connection is made to the moving contact by means of a very flexible copper-conducting strip.

Among the advantages obtained because of the loop type of construction is that large air gaps can be used between iron and loop which makes the element easy to inspect and eliminates the possibility of air-gap friction from foreign materials lodging in the gap. The efficiency of the design is such that very small burdens per phase are imposed. The voltage circuit requires 4.0 volt-amperes per phase at 115 volts and the cur-

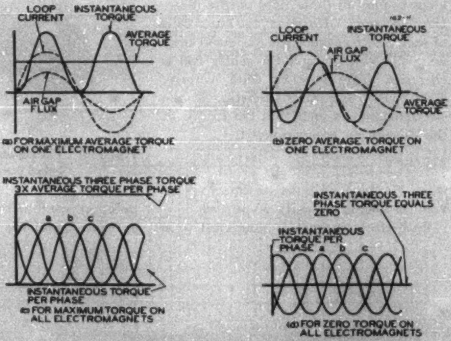

Figure 4. Torques produced in polyphase directional relay

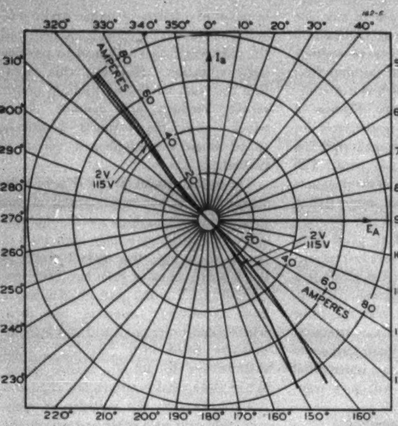

Figure 5. Phase-angle curves at 115 and 2 volts

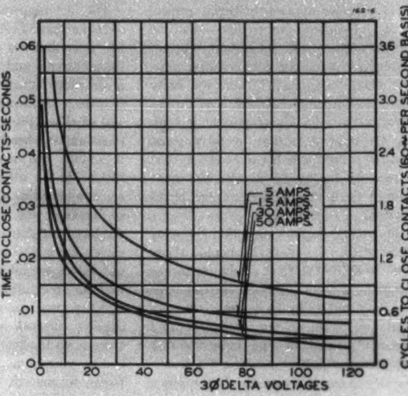

Figure 6. Timing curves of type H-3 directional relay

rent circuit, which also includes the phasing loops, requires 1.6 volt-amperes per phase at five amperes. The sensitivity of the relay is excellent, being less than one volt over a current range of 2.5 amperes to 100 amperes at the maximum torque phase angle. From the phase-angle curves shown in figure 5 it will be seen that the relay has adequate directional characteristics even at a very low voltage and high current.

Timing curves for the relay taken with a 0.030-inch contact gap are shown in figure 6. It will be seen that at 65 volts and above 15 amperes the timing is less than 0.6 cycle on a 60-cycle basis.

The directional relay is also made with a voltage-restraint element as shown in figure 7. The restraint element is mounted below the directional element and consists of three electromagnets and loops similar to those used on the directional element. However, the outer coils of each electromagnet are energized from one delta voltage, and the center coil is energized from another delta voltage. The phase-angle characteristic of the electromagnet is such that the torque of the element is proportional to:

$$E_1E_2 \sin \theta$$

where θ is the angle between the two delta voltages and is normally 60 degrees.

Each electromagnet is connected to a different combination of delta voltages so that a uniform restraint torque and balanced burdens are obtained. During a three-phase fault the voltage-restraint torque is reduced in proportion to the square of the voltage, so that for low voltages it is negligible. During unbalanced faults when any one delta voltage becomes zero, the restraint is automatically removed, because one of the applied voltages becomes zero on two of the electromagnets, and on the third electromagnet the collapsed voltage has made the sine of θ zero.

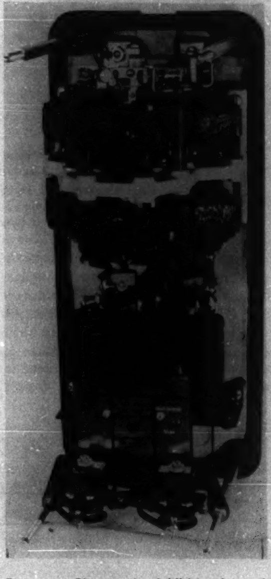

Figure 7. Photograph of HV-3 relay with glass cover removed

If it is desired to remove the restraint during a fault, it can easily be accomplished by opening any one supply lead to the restraint element. This applies single-phase voltage to all three electromagnets and the sine of θ becomes zero on all, so that there is no torque on any of them. The restraint is such that it requires ten amperes at normal voltage at the maximum torque phase angle of the directional relay to overcome the restraint torque.

In conclusion, the new polyphase inductor-loop directional relay has all the desirable characteristics inherent in the induction-disk type relay, with the additional ones of compactness, low burden, high sensitivity, and high-speed operation, which is difficult to obtain with the polyphase induction-disk type. With these outstanding advantages, it is believed that the new relay will replace the polyphase induction-disk type where formerly used and will be considered as an important advancement in relaying art.

Experience With Preventive Lightning Protection on Transmission Lines

S. K. WALDORF
MEMBER AIEE

Synopsis: Footing resistances for transmission line towers must be low for good operation, but it appears that no benefit results from reducing them below a certain limiting value characteristic of a given construction. This is because flashover can apparently be caused not only by excessive footing resistance drop, but also by the reactive drop accompanying rapid rates of current rise when tower currents are large.

The records seem to show that overhead ground wires provide better shielding than has been believed. Overhead ground wires and tower footing resistances co-ordinated with line insulation provide preventive protection which is highly efficient.

Operating experience indicates that lightning outages can be predicted fairly well from simple probability calculations.

I. Introduction

THE art of protecting transmission lines against lightning has advanced considerably in the last decade, but there are some phases of the problem which are still obscure. In analyzing the experience of the Pennsylvania Water and Power Company, which operates steel tower transmission lines at 66 to 220 kv, certain trends have appeared which are believed to be significant. It is the purpose of this paper to bring these findings to the attention of those interested in lightning protection in order that the apparent trends may be widely investigated and their validity established or disproved. The interpretation of results as given here, therefore, in no sense should be considered as final, but only as bases for further study.

Preventive lightning protection for transmission lines, as the term implies, is designed to prevent flashovers entirely as contrasted to remedial measures which are designed to minimize the effects of lightning. In this paper, preventive lightning protection is used in a special sense as the designation for the mounting of overhead ground wires on the same steel towers as the power conductors and the co-ordination of tower footing resistances with line insulation. Tower footing resistances on the lines referred to here have been almost exclusively reduced by the installation of buried counterpoise conductors of various lengths and number.

II. Extent of Experience

The Pennsylvania Water and Power Company first began to try preventive lightning protection on its transmission lines in 1931 with the construction of the Safe Harbor-Westport 220-kv line.[1] Since then two new lines have been constructed and five old ones improved using the same basic principles, but with variation in details.

In 1934, surge-crest ammeter links[2] were installed on the Safe Harbor-Westport-Takoma 220-kv line and since then their use has been gradually expanded until in 1939, 2,279 transmission towers on 318 miles of line have been equipped. These devices have permitted a relatively close check to be made of the efficiency of the lightning protection.

Surge-crest ammeter links have also been placed on 21 banks of 66-kv lightning arresters, two banks of 132-kv arresters, and one bank of 220-kv arresters.

III. Distribution of Current in Tower Members

For several years, there has been a total of 87 towers equipped with a pair of surge-crest ammeter links on each of the four corner or leg members of each tower. Since 1934, 209 sets of records have been obtained from these installations, of which 98 records are from towers believed to have been struck by lightning or adjacent to struck spans. The purpose of these observations has been to determine the error entering into the assumption that the tower current is four times the current in one corner leg.

The results of this study are given in table I. The sum of the four indications in the corner legs has been taken as the approximately correct tower current. The deviation from it of four times each of the four individual leg currents has been obtained. The deviations for each group of tower records in 5,000-ampere increments of tower current have been averaged in table I.

Although relatively few readings have been obtained when the tower currents were of the larger magnitudes, from table I it appears that the indications obtained on towers having a bracket on only one leg can be assumed to be fairly good approximations when the currents are in

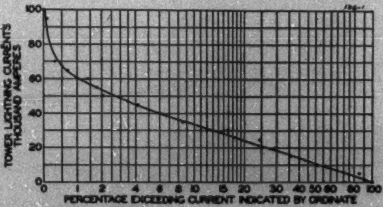

Figure 1. Distribution of 1,201 currents measured in towers believed struck by lightning (1934–39)

Paper 41-36, recommended by the AIEE committee on power transmission and distribution, and presented at the AIEE winter convention, Philadelphia, Pa., January 27–31, 1941. Manuscript submitted July 23, 1940; made available for preprinting December 10, 1940.

S. K. WALDORF is test engineer for the Pennsylvania Water and Power Company, Baltimore, Md.

1. For all numbered references, see list at end of paper.

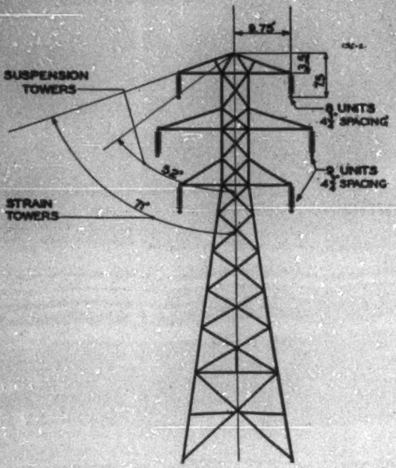

Figure 2. Minimum shielding zones required of single overhead ground wire on suspension and strain towers of the Holtwood–Coatesville 66-kv line

the upper range, that is, greater than about 40,000 amperes.

In 45, or 22 per cent of the 209 sets of observations, the magnetic links on all legs of a tower did not have the same polarity of magnetization. It is believed that records of this type are due to successive strokes of opposite polarity, occurring either close together or with an appreciable elapsed time between them. As they have been found only in the lower current ranges, it is not likely that the large deviations in indication which they cause greatly affect the analyses given here.

It has been suggested that tower currents, as taken from records obtained in the four corner leg members of a tower, be multiplied by a factor ranging from about 1.3 to 2 to account for the current passing through the cross braces of the tower.[3] Because of the uncertainty of the value of the factor,[4] and the unequal distribution of lightning current in tower legs as shown in table I, none has been used in the data reported here.

IV. Distribution of Tower Currents of Various Magnitudes

In the period of 1934–39, a total of 1,201 tower currents has been recorded where it is believed that lightning struck. The tower current in each case was recorded as four times the current indicated in one of the four tower legs, or as the sum of the four indicated leg currents, depending upon the number of SCA links installed at the respective tower. The data have been plotted in figure 1.

V. Distribution of Lightning Strokes Along Lines

The records show that the 1,201 strokes which have terminated on the lines of the system have been well distributed. For instance, on the Safe Harbor-Perryville 132-kv line there were not over three consecutive towers which were not struck during the five-year period of the study. On the Safe Harbor-Westport-Takoma 220-kv line where the stroke records have been kept for six years, five is the maximum number of consecutive towers where no strokes have occurred. Although a considerable length of a line may not be struck during the first observation year, in general, it has been found that during succeeding years the maximum length of unstruck line is reduced to a few spans.

VI. Lightning-Stroke Frequency

In table II, the variations in frequency of occurrence of lightning are apparent. It will be noticed that the number of recorded strokes to a line will vary in the ratio of almost as much as three to one from year to year. During a year when the number of strokes to one line may be relatively high, those on another may be very low, as for instance, in the years 1935 and 1938. The average number of strokes per hundred miles of line per year is 126 for rights-of-way having only one line. This value cannot as yet be considered as final because the averages for the individual lines still deviate from it by as much as 29 per cent.

VII. Flashovers

Examination of the lightning current records of the Holtwood-Coatesville 66-kv line obtained during the three years before the installation of counterpoise re-

veals no regular behavior. There were 21 single- and double-circuit tripouts during 1935, 20 during 1936, and 17 during 1937. The individual effects of poor grounding, insulation, and shielding are indeterminate from the data. However, after the installation of counterpoise and the improvement of insulation, the relative importance of the several protection factors became more apparent. The Holtwood-Coatesville line is the only line of the company on which surge-crest ammeter links were placed prior to the installation of counterpoise.

Data on the cases since 1934 in which flashover occurred on lines provided with preventive protection are given in table III.

It will be noticed that in six of the seven cases the indicated tower currents are greater than 50,000 amperes and in five of the cases they are of the order of 60,000 amperes. The latter group suggests that currents around 60,000 amperes are just above the maximum that can be carried without flashover by towers of the type used on the 66-kv lines. In 1937, a tower of the York line carried an indicated current of 63,200 amperes without flashover, which is the only case where a tower of the 66-kv lines carried current in excess of 50,000 amperes without flashover occurring. The tower footing resistance was seven ohms in this case, giving a calculated tower potential of 440 kv, 45 per cent of the normal safe maximum, or flashover level.

In the case of tower 99 of the Coatesville line in table III, it appears that the top conductor of circuit 13 was struck by lightning, causing the flashover. Tower 99 is a suspension tower.

These data on flashovers seem to show that there is a limiting current which towers can carry, irrespective of measured footing resistance. Due to recognized errors in the method of measurement of tower current, the results are not accurate, but a trend is indicated. For five out of six instances, flashovers occurred on 66-kv towers when tower currents were indicated in the order of 60,000 amperes. On the 132-kv line, the flashover recorded in table III was the only one which occurred in three cases where currents were in excess of 50,000 amperes. It is not clear whether the flashover was due to a combination of circumstances, the ground resistance of the counterpoise being relatively high within 300 feet of the tower (about $16^1/_2$ ohms) and a tall tower structure, or due to inadequate shielding. The available data seem to favor the first explanation.

The present-day theory[4] of the behavior of circuits carrying lightning surge currents indicates that there are two voltage effects present. One is the resistance drop which is at a maximum when the surge current is maximum, and the other is the reactance drop which is at its maximum when the current is changing most rapidly. These maxima obviously cannot occur at the same instant, but the maximum circuit voltage will occur somewhere in the interval between the instants of the maxima of the two component drop voltages. Either of the two may predominate, or their effects may be of equal importance, depending upon circuit conditions. From the flashover data presented here, it appears that when conditions are such as to give an indicated tower current of about 60,000 amperes, the rate of current change is sufficiently great to make the reactance component of drop appreciable. For towers, grounding, and insulation of the type used on the 66-kv lines considered, it apparently becomes predominant to the extent of almost always causing flashover. For towers, grounding, and insulation used on the 132-kv line, the reactive effect is appreciable, but apparently becomes of consequence only when tower heights and footing resistances are relatively great.

If future experience bears out the trend which now appears, there will be no advantage in reducing footing resistances below six or seven ohms for the type of 66-kv towers discussed here. Other types of construction will probably be found to have other values for the lowest worth-while limit of footing resistance.

VIII. Efficiency of Protection

The efficiency of a protective scheme can be computed by taking the ratio of the number of times strokes did not cause interruptions to the number of strokes. The efficiencies of the lightning protection during the years that the lightning current study has been in progress on the several lines are given in table IV. The true efficiencies may be slightly higher than those given in table IV because of

Table I. Deviation From Equal Division of Lightning Current in Tower Legs

possible multiple records or weak records on the surge-crest ammeter links.

It is of some interest to note the extremely high efficiency of protection which is required to limit to a low figure the number of tripouts over a period of years.

IX. Efficiency of Shielding

The relative merits of one and two overhead ground wires and of the many possible positions in which they may be placed have been studied by many investigators at great length theoretically, and in the laboratory.[6] From the lightning current data which have been collected, it is possible to evaluate the efficiency under operating conditions of the various arrangements used on the lines to which reference is made here.

For an overhead ground wire to shield a line conductor from direct strokes, the line conductor must lie within the protective zone of the ground wire. In figures 2, 3, 4, and 5 are indicated the minimum protective shielding zones that the respective overhead ground wires must provide. Where a single overhead ground wire has been installed, the required protective zone is wider for a strain tower than for a suspension tower, as shown in figure 2. This is because the conductor is at the height of the cross arm on a strain tower, and below the cross arm on a suspension tower by the length of an insulator string. Where two overhead ground wires have been installed on the newer lines of the company, the overhead ground wires have been elevated at strain towers to maintain the same clearances above line conductors as is provided at suspension towers. The protective zones required on strain and suspension towers having such construction are, therefore, the same. (See figures 3, 4, and 5.)

From the number of flashovers and recorded strokes to the several classes of transmission lines, the minimum efficiencies of the shielding arrangements can be computed. The number of flashovers which have occurred are known accurately for practical purposes from the tripouts which have occurred. The recorded strokes to a line may be slightly less than the actual number due to more than one stroke affecting a set of links between inspections and calibrations. Ignoring some strokes because of the weak magnetic effect produced will also affect the number of reported strokes in the same manner.

When a flashover occurs, there may be some question of the cause being inadequate shielding or high-tower potential. If some flashovers are believed to be caused by excessive footing resistance or tower current, there will be less chargeable to imperfect shielding.

Efficiency of shielding =

$$100\left(1-\frac{\text{outages}}{\text{strokes}}\right)\text{per cent}$$

The maximum probable efficiency is obtained when the number of outages believed due to poor shielding is used in the expression, and the minimum efficiency when the total number of outages is used. The latter figure is, of course, the pessimistic one.

It can be seen in figures 3 and 4 that the shielding conditions on the 220-kv and 132-kv lines are practically identical. In table V the data for these two classes of towers are combined.

The behavior of the lines with two overhead ground wires is in agreement with the behavior predicted from surge tests on miniature models, but that of the line with one overhead ground wire is much better. In the latter case the shielding on the suspension towers is theoretically superior to that on the strain towers, but their behavior during the period of study has been practically the same.

X. Comparison of Calculated Probable Outages and Actual Outages

Some years ago Lewis and Foust[7] suggested that, as a result of their studies,

Table II. Strokes to Lines

Average strokes per 100 miles of line per year for all lines except the last in the list is 126.

flashovers of shielded transmission lines only occur when tower potentials exceed the insulation strength of the given line. The tower potential in each case was taken as the product of tower footing resistance and tower lightning current. Based on this theory a method was suggested several years ago by the present writer for calculating the probable outages of shielded transmission lines.[8] In table VI a comparison is made between the actual flashovers experienced on the several lines and the calculated behavior.

For all but one of the lines, the actual performance has not been as good as the estimated. The record of flashovers given in table III shows that flashovers can be caused by tower currents less than those predicted from the theory based on tower footing resistance drop.

As the original empirical Lewis and Foust rule,[7] the data used in the probability calculations, and the records found when flashovers occurred are all based on the same measurement method, any discrepancies between calculated and actual outages do not seem to be attributable to neglecting the current carried by tower cross braces. The discrepancies are, therefore, thought to result from the impedance drop in the tower structure and footings being appreciable.

To make the probability calculations conform to field experience, the theory must be modified to state that flashover does not occur unless the product of tower current and tower footing resistance exceed the insulation level of the line, or unless the tower current exceeds the characteristic safe current for the given tower and grounding arrangement. The characteristic safe current seems to be around 60,000 amperes for the 66-kv lines. From the circumstances attending the single flashover which occurred on the 132-kv line, from the relative insulation strengths of the 66- and 132-kv lines, and from other data, it is estimated that the characteristic safe current of this 132-kv line is probably around 90,000 to 100,000 amperes. Experience with the 220-kv lines seems to indicate that the safe characteristic current of the towers, grounding, and insulation used on these lines probably is in excess of those occurring in nature. The only flashover experienced on the 220-kv lines occurred in 1933 at a tower having a footing resistance of 25 ohms. This was before the lightning current studies were begun, but the flashover can be accounted for on the basis of the original Lewis and Foust theory by assuming a tower current of 100,000 amperes, a value which has been measured several times in the field.

Table III. Flashovers on Transmission Lines Provided With Preventive Lightning Protection

Line and Tower	Year	Tower Current in Amperes	Tower Footing Resistance in Ohms	Tower Height in Feet	Tower Potential (I×R) (Kv)	Ratio of Tower Potential to Flashover Level
Holtwood-York 63 (66 kv)	1937	58,400	13.8	75	805	0.82
Holtwood-York 145 (66 kv)	1937	60,000	19	76	1140	1.16
Holtwood-Coatesville 40 (66 kv)	1938	64,400	17.2	73	1108	1.30

Holtwood-Coatesville 66 kv				
Before improvements	2†	37	55	33
After improvements	2	3	113	97.4
Holtwood-Baltimore 66 kv (Two lines on one right-of-way)	1	1‡	65	98.4

*Single, double, and triple circuit tripouts.

**A flashover of this line occurred in 1933 before the lightning current studies were begun. The estimated efficiency for the entire eight years of operation is:

$$100\left(1-\frac{1}{8/5\times 482}\right)=99.9 \text{ per cent}$$

†Stroke records are complete for only two years (1936 and 1937).

‡Not included is one tripout which occurred before the installation of counterpoise was completed in 1930.

The probable outages for the lines have been recalculated in table VII using the estimated safe characteristic tower currents given above as the maxima that can be carried under any circumstances. The calculations may possibly be further refined in the future when tower and footing impedances become evaluated and their effect in combination with footing resistance is determined quantitatively.

XI. Lightning Arrester Records

Surge-crest ammeter links have been mounted on the lightning arresters at Highlandtown substation in Baltimore since 1935. These arresters are connected to the four 25-cycle, 66-kv circuits of the two Holtwood-Baltimore lines. Each year since their installation, except 1936, they have indicated some current in at least three of the four arrester banks. The maximum current recorded was 2,600 amperes in 1937.

Similarly, arresters connected to other 66-kv circuits have carried small currents from time to time. The largest current recorded was 7,400 amperes in 1939 in the arresters connected to circuit 83 at Violet Hill substation in York. Circuit 83 is an unshielded wood-pole line of the Metropolitan Edison Company connecting through the high-tension bus at the substation to the Holtwood-York 66-kv line.

It is interesting and of some importance to note that during three seasons of study, no indications have been obtained of discharges through any of the four banks of arresters connected to circuits protected by two overhead ground wires and buried counterpoise systems.

XII. Summary

1. Because of the large number of observations, 3,289, which have been made during the six years of study of lightning currents, some confidence can be felt that the data are fairly representative of the several effects of lightning. Some uncertainties still exist in the data, as for instance the effect of tower cross braces on the measurement of tower currents.

2. The distribution curve of the various magnitudes of currents in towers believed

Table V. Efficiencies of Shielding

Type of Line	Years of Record	Number of Strokes	Number of Outages	Estimated Strokes to Conductors	Probable Efficiencies of Shielding Minimum (Per Cent)	Probable Efficiencies of Shielding Maximum (Per Cent)

*Includes only years of lightning current study. See table IV.

to have been struck by lightning has been established from 1,201 records. The curve can be used satisfactorily for purposes where the error due to cross braces is not objectionable. Considerable confidence can be placed in the general shape of the curve.

3. Over a period of years it appears that all sections of the transmission lines of the Pennsylvania Water and Power Company are struck by lightning, there being no localities that are immune.

4. The average number of strokes to the transmission lines studied is 126 per 100 miles per year. The actual number of strokes to a given transmission line, however, may vary in the ratio of as much as three to one from year to year. This variation emphasizes the need for examining lightning experience records for a period of several years before any conclusions are reached about lightning phenomena.

5. Analysis of the flashovers which have occurred on lines having overhead ground wires and buried counterpoise systems indicates that flashovers can be caused not only by the ground resistance drop being greater than the insulation strength, but also by the reactive drop due to the rapid rates of current rise which seem to accompany heavy tower currents. On the observed 66-kv lines this latter phenomenon seems to be of critical magnitude when the indicated tower currents have been around 60,000 amperes.

Table VI. Comparison of Actual and Probable Outages

Probable Outages Calculated on Basis of Lewis and Foust Theory as Originally Presented[7]

Line	Years of Record	Lightning Outages Per Year Actual	Lightning Outages Per Year Probable
Safe Harbor-Westport-Takoma 220 kv	8	0.13	0.014
Safe Harbor-Riverside 220 kv	2	0	0*
Safe Harbor-Perryville 132 kv	5	0.2	0.0078
Holtwood-York 66 kv	4	0.5	0.29
Holtwood - Coatesville 66 kv	2	1.5	0.68
Holtwood - Baltimore 66 kv (Two lines on one right-of-way)	1	1	0.2

* Does not include section 1.03 miles in length where there are no overhead ground wires.

6. Because of this latter phenomenon it appears that no advantage accrues from reducing tower footing resistances on such lines below approximately six ohms. This figure allows for suspected inaccuracies in the measurement of tower lightning currents and footing resistances. It is thought to be desirable that this value of footing resistance be obtained within not more than 200 or 300 feet of the tower base.

7. Operating experience shows that the arrangement of the two overhead ground wires on the newer lines of the company provides practically perfect shielding, that is, probably within less than 0.1 per cent. The experience with a single overhead ground wire is superior to that predicted from laboratory models. The record shows the shielding to be effective for about 98 or 99 per cent of the strokes contacting the Holtwood-Coatesville 66-kv line.

8. Preventive protection embodying the use of overhead ground wires and buried counterpoise installations co-ordinated with line insulation has been shown to be very effective. Since this work has been carried out completely on the 220-kv lines it has been 100 per cent effective. It has been 99.6 per cent effective on the 132-kv line and about 98 per cent effective on the 66-kv lines.

9. Discrepancies were found in the comparison of actual and calculated probable lightning outages. These have been traced to the phenomenon of a maximum surge current which a given construction can apparently withstand irrespective of the measured tower footing resistance.

10. The lightning arresters connected to transmission lines provided with effective preventive protection are seldom called upon to carry lightning discharges, and then they are apparently of small magnitudes.

High-Voltage Bushings Designed to Meet Modern Service

T. F. BRANDT
MEMBER AIEE

H. L. RORDEN
MEMBER AIEE

Introduction

BUSHINGS are a very important part of over-all system insulation. Since all of the power transmitted from station to station and station to consumer passes through a great many bushings the majority of which are a part of vital equipment such as transformers, breakers, etc., it is immediately apparent that system-service continuity depends, to a large degree, upon satisfactory bushing operation. Early bushing designers were handicapped by a lack of operating history and high-voltage testing facilities. However, in spite of these handicaps they developed some sound designs as evidenced by the many 25- to 30-year-old bushings in satisfactory service today. In these early bushings porcelain was one of the principal dielectrics.

Comprehensive studies of porcelain oil-filled bushings have been made to improve both the electrical and mechanical characteristics. As a result of these studies a better understanding of the internal and external electrostatic field conditions has resulted, and a new method of voltage grading developed. Mechanical improvements have been made which not only simplify construction, but stabilize the electrical characteristics by maintaining the over-all assembly close to its original condition. These developments will be discussed here.

Control of Electrical Characteristics in Bushing Design

Design Requirements

From an electrical standpoint, a bushing must have adequate internal insulation to provide a safe margin between internal puncture and external flashover. There also should be no corona formation at operating voltage and radio interference must be kept at a minimum. The over-all electrical characteristics of a bushing should be stabilized in so far as they affect operating performance. A design which has excellent electrical characteristics in the laboratory, but is subject to change under operating conditions, is undesirable if these changes adversely affect the performance. Extensive tests have been made in the laboratory and operating records have been carefully checked to guard against this possibility.

A bushing must provide sufficient insulation in two ways. First, it must have the required external flashover voltage commensurate with its rating and the insulation level of associated equipment, and secondly, the internal puncture strength must have a satisfactory margin over the external flashover. Since external flashover of a bushing is through a surrounding medium, such as the air around the upper or weather end, full consideration must be given the characteristics of this medium to obtain the balanced design necessary for stable electrical performance.

Porcelain oil-filled bushings use insulating materials of differing dielectric constants or flux-carrying capacities. With insulation in series there is a tendency for those of lower dielectric constants to have imposed relatively greater portions of the total voltage. Accordingly, it is essential that high localized stress be avoided in those insulating zones having low dielectric constants. This applies to the medium surrounding the bushing, as well as the insulation within it.

Means of Controlling Characteristics

In order to determine the effectiveness of voltage grading or electrostatic field-controlling arrangements a series of impulse and 60-cycle studies were made. Many assemblies were tested, but only representative types having practically the same striking distance will be discussed here. These are shown in figure 1.

In figure 2 are shown photographs of corona due to 60-cycle overstress on the assemblies of figure 1. Figure 3 shows photographs of the field patterns around these same assemblies as indicated by corona from impulse-suppressed discharges. Complete electrical data on the above assemblies, along with voltages applied in the various photographs, are given in table I.

In figure 1*a* is shown a porcelain tube with a metal cap and flange, but *without* a central conductor. Appreciable 60-cycle corona can be seen at the cap in figure 2*a*, while a uniform field pattern exists in figure 3*a* for both polarities. This assembly is included to show the radical change in the field when a conductor is passed through the center of the tube. Figure 1*b* is the same as figure 1*a* except *with* a central conductor added. Heavy 60-cycle overstress is apparent in figure 2*b* immediately above the metal flange and figure 3*b* shows the field overstress due to suppressed discharges.

The difference between the positive and negative field patterns of figure 3 is in accord with observations made on the study of dielectric fields existing between various types of electrodes in air.[1] It is possible to control these stresses to some degree by the shape and arrangement of electrodes and by various methods of grading. The central conductor of figure 1*b* has changed the electrostatic field so that the air at the edge of the flange is highly overstressed. This overstress is due to the low dielectric constant or flux-carrying capacity of air as compared to porcelain. The air space between the central conductor and the porcelain is subject to overstress for the same reason. These two regions are the cause of unstable flashover and radio-interference characteristics in this type of bushing.

In contrast with figure 2*a* there is no overstress at the cap in figure 2*b*. The central conductor shields the cap since most of the electrostatic flux lines emanating from the flange terminate on the central conductor well below the cap. Figure 4 shows the approximate field condition for figure 1*b*. Initial overstress starts in the air immediately above the flange at *A*. As the voltage is increased, the air becomes ionized, forming a conducting envelope over the porcelain surface to a point where flashover occurs at a rather low voltage.

In figure 1*c* is illustrated a typical solid porcelain bushing. Figures 2*c* and 3*c* show its 60-cycle and impulse corona patterns, which are similar to those of figures 2*b* and 3*b*. The performance of the figure 1*c* design can be improved somewhat by changing the porcelain configuration.

Oil-filled bushing designs readily adapt themselves to the elimination of localized overstress. For example figure 1*d* is a

simple oil-filled assembly with no grading means other than its porcelain configuration. The 60-cycle corona in figure 2*d* shows the heavy overstress immediately above the flange. The approximate field condition around the flange area of the figure 1*d* design below the point of excessive corona is shown by figure 5. The inside air between the conductor and the porcelain has been replaced by a combination of oil and wrapped insulation, thereby preventing overstress in this area. However, no effort has been made to control the field at the mounting flange, thereby resulting in two highly stressed regions. One is at *B*, figure 5, inside the bushing where the flange terminates in the oil; the other is at *A*, the outer exposed edge of the flange. The voltage gradient at *B* is higher than at *A*. However, since the dielectric strength of the oil at *B* is appreciably higher than that of the air at *A*, overstress appears first at *A* at a lower voltage gradient.

This overstressing at *A* establishes a conducting envelope of ionized air with increasing voltage. It does not progress up the bushing as far as on figure 2*b* but stops under the first petticoat. This is due to the conducting envelope assuming a form of grading means, as shown by figure 6. This same condition is shown in figure 2*c* where overstress stopped abruptly under the porcelain petticoat. This has not been generally appreciated and many bushings have been made in both the solid and oil-filled types with the region from *A* to *C*, figure 6, unstable, thereby involving possible radio interference.

Figure 1*e* is similar to figure 1*d* except that a capacity grading means in the form of an insulation-wrapped metal core is incorporated. The metal core and the metalizing on the porcelain tube are electrically connected to the flange. Since the wrapped metal core extends up inside the bushing, it partially shields the outside exposed edge of the mounting flange. At the same time it reduces the voltage stress in the oil at the inside edge of the flange and at the top edge of the metalizing on the porcelain tube. Covering the metal with insulation is essential for proper field control. Tests on various forms of uninsulated metal grading means have proved them to be relatively ineffective.

The approximate field condition of figure 1*e* is shown by figure 7. The metalized, ground potential surface on the porcelain shorts out the highly stressed oil at *B* in figure 5. The point *A* is not completely shielded since it goes into corona as shown by figure 2*e*. However, the corona is materially reduced from that shown on figure 2*d*. In table I, figures 1*d* and 1*e* are seen to have practically the same 60-cycle flashover although an appreciable difference exists in the radio-interference values. This is because at flashover voltage the external field control set up by the conducting envelope of corona in figure 2*d* and the grading means of figure 2*e* are equally effective in so far as flashover voltage is concerned.

In the lower operating voltage bushings, namely 69 kv and below, cover opening diameters have been somewhat restricted. The problem here has been to develop the most efficient methods of using the available space. Various voltage grading arrangements have been used, but most of them require space which can be used better for effective insulation between the central conductor and ground. A newly developed method, not requiring this, is a form of resistance grading by means of conduction glaze applied directly to the porcelain surface. Figure 8 shows the approximate field of the figure 1*f* design which utilizes this resistance grading.

Figure 7, the type used in figure 1*e*, can be called an auxiliary means since it is not integral with the porcelain. Figure 9 is an effective field-controlling arrangement used on present high-voltage bushing designs of ratings, 92 kv and above. This type, formed integral with the porcelain, is very effective where space permits its use. The types in figures 7 and 9 function by means of their configuration and the voltage drop through a dielectric. Figure 8 functions because of the voltage drop through a high resistance. There must be enough voltage drop along the conduction-glazed surface from *D* to *E* to prevent overstressing at both *D*, the

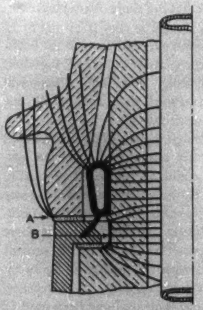

Figure 7. Field pattern for figure 1e

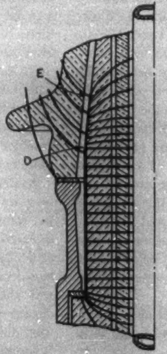

Figure 8. Field pattern for figure 1f

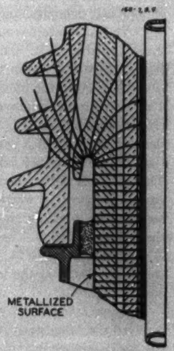

Figure 9. Field pattern for figure 11

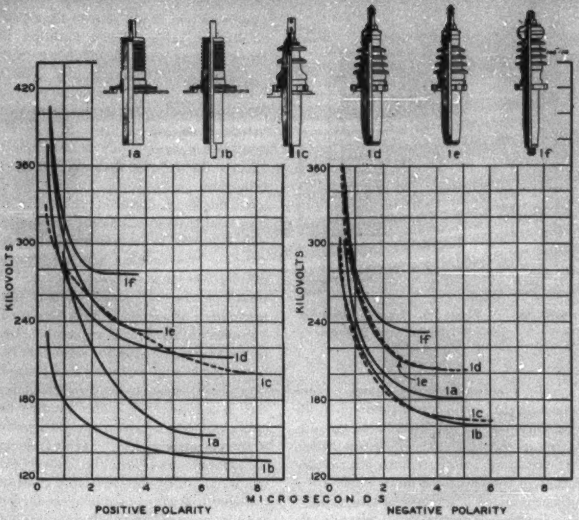

Figure 10. Volt-time characteristics of assemblies in figure 1

end of the metalizing, and at *E*. This means that the resistance of the conduction glaze region from *D* to *E* must be maintained within definite limits by careful manufacturing control. Likewise, the conduction glaze must have permanently stable characteristics.

Figure 1*f* illustrates a modern bushing using resistance grading. Figure 2*f* shows a very light glow between the petticoats with 120 kv, 60 cycle applied on the bushing. This shows the absence of localized overstress outside the bushing. The radio interference (table I) indicates the absence of the internal overstress. Figure 8 shows the field condition discussed in the previous paragraph. This construction improves the electrical characteristics materially by approaching the uniform field of a sphere gap rather than the concentrated field of a rod gap. This is particularly emphasized by the curves in figure 10 where this design is seen to have a rather high and flat volt-time characteristic. The other extreme is the design of figure 2*b* whose poor field condition results in the lowest volt-time curve of figure 10.

Bushings rated 92 kv and above have received the same study, and figure 11 is the one developed for 115-kv service. It is provided with capacitance grading of the type shown in figure 9, and gives proportionately the same performance as figure 1*f*. Since these modern designs are stable at voltages considerably in excess of their rating, it is safe to assume that their characteristics will remain unchanged under normal operating conditions.

Mechanical Improvements

Excellent electrical properties are of little value if the mechanical design does not maintain the bushing at or near its original condition for a long period of time. This requires, primarily, sturdy construction with efficient gasket joints and one that will maintain a stable condition of the oil. Figure 11 shows a modern bushing having these characteristics.

An early design is shown by figure 12 where all of the external parts of the bushing were completely cemented together. If gasket leaks or other mechanical troubles developed, there arose a difficult maintenance problem.

A later design, shown in figure 13, could be more easily maintained since the gasket joints could be tightened or readily replaced. However, the large metal parts cemented to porcelain presented occasional problems. In the first place there was the possible chance of a cement change with time where joint *A*, figure 13, was directly exposed to the weather. Weatherproof coatings have been used to prevent cement deterioration, but under extreme conditions they have been found wanting. Also a differential thermal expansion existed between the metals and porcelain. Special treatment of the cement joints to compensate for thermal expansion has also been tried. There are many thousands of large oil-filled bushings such as those of figures 12 and 13 in service which have given a good account of themselves, but gasket leaks and damaged porcelain are not uncommon.

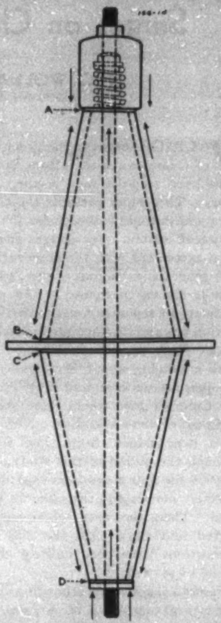

Figure 14. Schematic view of compression assembly showing how gaskets are kept under compression

Several years ago the full compression-assembled bushing was introduced. This produced a very rugged assembly, eliminated external cement joints, and kept the gasket joints permanently oil-tight. It is a well-established fact that most gasket materials kept under constant pressure between mating surfaces remain oil-tight indefinitely. Formerly, gaskets had to keep themselves tight. To illustrate this, when the gaskets in bushings such as figure 13 were originally tightened, the material, due to its initial resilience, exerted a strong back pressure against the mating surfaces. However, this back pressure for practically all gasket materials diminishes with time. In addition some shrink or take a permanent set. In any event, in a relatively short time the gasket joint is not as effective as when first made.

The full-compression assembly shown

*Wave is "chopped" by parallel rod gap, allowing voltage considerably above critical flashover value.

in figure 11 compensates for all gasket variations since the mating parts are continually acted upon by the compression spring in the oil reservoir. This is shown schematically in figure 14 which indicates how the compression loading of the spring is transmitted to the various gasket surfaces at *A*, *B*, *C*, and *D*. The compression spring must have adequate "pickup" or deflection so that any shrinkage of the gaskets will not release the spring enough to affect its loading appreciably.

With dependable gasket joints now available, it is possible to have a completely sealed bushing. This has been done over an entire range of oil-filled porcelain bushings to secure a stable oil condition. Moisture, oxygen, and sunlight are all detrimental to insulating oil, but by completely isolating the oil from them, its dielectric properties remain practically constant. Where it is desired to check the oil level occasionally, especially in the larger bushings, a magnetic oil level indicator is used. This affords a definite indicating means without exposing the bushing oil to sunlight, moisture laden air, etc.

In order to keep the pressure in the bushing within reasonable limits, adequate space in the top oil reservoir shown must be provided for oil expansion due to temperature changes. The compression spring arrangement must be adequate to keep the gasket joints tight against the various pressures in the bushing.

Surges on Chicago 12-Kv System

F. O. WOLLASTON
ASSOCIATE AIEE

H. J. PLUMLEY
ASSOCIATE AIEE

VOLTAGE surges on the 12-kv system of Commonwealth Edison Company have been recorded and studied for 20 years. This paper presents the Chicago data and outlines a theory for the explanation of system overvoltages that is in good agreement with the observations.

A geographical layout of the 12-kv system is shown in figure 1. At present there are six separate zones consisting of a station bus and its associated radial 12-kv lines. Each zone has about 50 or 60 lines averaging about three miles long. All lines are underground cable except in the Calumet zone where there are some sections of overhead line. New zones have been added from time to time through the period of this study. Prior to 1928 the four zones then existing were directly connected through 12-kv tie lines. These ties were subsequently removed and since 1928 the only interconnections have been indirect through the 66-kv system.

Figure 2 is a schematic one-line diagram of a typical bus layout for any one of the six generating or distributing stations in Chicago. The two basic features of every 12-kv zone in the system are (1) independent feed of bulk power from each of the two independent 66-kv systems and (2) provision for splitting the local 12-kv system into two independent systems by the operation of sectionalizing breakers. Two types of grounding are used in the zones involved in the surge studies. In one type a derived neutral transformer having an inductive impedance of three ohms is used. In the other type, one generator neutral is grounded through three ohms of resistance.

Spark-gap installations have been maintained on the system since 1919. The present locations are indicated in figure 1. The device is shown schematically in figure 3. A sphere gap in series with a fuse, a protecting resistor, and a recorder is connected between each phase of a 12-kv substation bus and ground. The surge of current caused by a gap flashover operates a simple solenoid connected to the pen of the clock-driven recorder, leaving a jog on the chart which shows when the overvoltage occurred and which phase it was on. The magnitude of the overvoltage remains unknown, except that the breakdown of the gap establishes its lower limit. The gap settings have been adjusted from time to time through the 20 years of the study to cover the range 1.85 times normal crest voltage to 3.5 times normal crest voltage. As the gap settings were increased there was a corresponding decrease in the number of overvoltages recorded, until at 3.5 times normal crest voltage no records were obtained. The time of occurrence of each spark-gap operation is carefully correlated with the daily log of switching operations and the oscillograph records of abnormal conditions in the system.

The oscillograph records provide another distinct line of attack on overvoltage phenomena by facilitating the study of simultaneous or "sympathetic" failures. Such occurrences consist of a failure in one part of the system, followed almost immediately by one or more failures elsewhere in the same system, perhaps several miles distant from the original failure. The original failure is referred to throughout this paper as the primary failure while the one or more failures that may occur almost simultaneously are referred to as secondary failures. The terms primary and secondary as used here should not be confused with the same terms used to designate two transformer-coupled circuits. Questions that naturally arise are: (*a*) Is the secondary failure caused by a brief transient or by the increase in 60-cycle voltage on two phases incidental to the grounding of the faulted phase? (*b*) If transients are present, what is their nature? (*c*) Are the secondary failures associated with the switching that clears the original failure, or do they precede such switching? The routine high-speed records, supplemented by staged tests, have assisted in elucidating these matters.

General Conclusions

From the studies of records of over 700 spark-gap operations, 54 simultaneous failures of lines or apparatus in service, and 15 staged tests in which faults were thrown on the system, the following conclusions have been drawn:

1. The maximum magnitude of overvoltages on this system is about 3.5 times normal crest voltage.

2. The overvoltages of highest magnitude are associated with system failures and are best understood by use of the "cancellation-wave" theory; the highest transients occur at the inception of the fault, not during the switching that clears the fault.

3. Overvoltages associated with routine switching are amenable to the "cancellation-wave" theory, but are usually of smaller magnitude than those associated with failures and are therefore of less interest.

4. Most secondary failures in simultaneous failures are caused by the overvoltages mentioned in conclusion 2.

Paper 41-51, recommended by the AIEE committees on power transmission and distribution and protective devices, and presented at the AIEE winter convention, Philadelphia, Pa., January 27–31, 1941. Manuscript submitted November 25, 1940; made available for preprinting December 12, 1940.

F. O. Wollaston is supervising research engineer and H. J. Plumley assistant research engineer for the Commonwealth Edison Company, Chicago, Ill.

5. The overvoltages on the Chicago 12-kv system are essentially power-frequency phenomena.

6. When an overvoltage condition is set up, it is propagated throughout all parts of the system that have direct metallic connections, but is strictly confined to such metallically connected parts.

7. Secondary failures occur only in insulation that is deteriorated to the point where it will not withstand (*a*) 60-cycle overvoltage of value 1.73 times normal crest to ground applied for the duration of a system fault to ground, (*b*) a few cycles of transient overvoltage having a maximum magnitude of 3.5 times normal crest to ground.

8. Zones having a derived neutral ground, which is essentially inductive, have more and higher transient overvoltages than zones having the generator neutral grounded through resistance.

9. The number and magnitude of overvoltages recorded in the zone having some sections of 12-kv overhead line, excluding overvoltages due to lightning and unknown causes, were about the same as for the zones in which all the lines were underground.

Spark-Gap Data

The data on system overvoltages obtained in the period 1919–28, when all the 12-kv zones were directly interconnected, are shown in figure 4. A few surges exceeded 3.2 times normal, which was the highest gap setting used in this period. The recording devices were needle gaps. Similar data for sphere gaps (one-inch spheres) are given in figure 5 for the period 1932–38, when the zones were not directly interconnected. A few overvoltages exceeded three times normal, but none exceeded 3.5 times normal. The latter setting was maintained at all spark-gap installations for about $1^1/_2$ years. From this it appears that the maximum overvoltages on the system do not exceed 3.5 times normal. The needle-gap and sphere-gap data both show that overvoltages associated with failures are usually higher than overvoltages associated with routine switching.

The correlation of overvoltages with failures is shown in figure 6. About 40 per cent of all faults are accompanied by overvoltages of twice normal or greater. Only about six per cent of the faults are accompanied by overvoltages exceeding three times normal.

Comparing figures 4 and 5, it is seen that more overvoltages of a given magnitude occurred during 1919–28, when needle gaps were used, than during 1932–38, when sphere gaps were used. The reasons are threefold:

(*a*). The zones were directly interconnected in 1919–28, so that a system disturbance might leave a record at every spark-gap installation, instead of at only one or two as was the case for 1932–38.

(*b*). There were many more failures, hence many more chances of having system overvoltages, in the 1919–28 period than in 1932–38.

(*c*). Needle-gaps have a greater tendency than sphere gaps to flash over at less than the nominal setting as a result of ionization and accumulation of dust in the gap.

Figure 1. Chicago 12-kv system

It may also be inferred from these facts that the overvoltages were not high-frequency phenomena, since the time lag of the needle gaps apparently did not suppress them appreciably. More reliable evidence to prove the point is presented later in the paper.

Concerning the accuracy of the surge-recording devices used in the study, it is thought that sphere gaps are very reliable, needle gaps somewhat less so, and klydonographs rather inaccurate. Capacity-coupled klydonographs were tried for about a year, but the records were found to be worthless. The klydonographs were connected in parallel with the needle gaps. Comparison of the magnitudes indicated by the two methods for each recorded surge showed that the klydonograph installations were not reliable.

Simultaneous Failures

From the standpoint of the operating engineer, surge phenomena are of practical importance principally because of the electrical failures of lines and equipment that are caused by them. The occurrence of simultaneous failures is the most common manifestation of troubles caused by surge voltages. During the period 1923–39, there were 54 sets of simultaneous failures on the Chicago 12-kv systems. Forty-nine were double failures, each involving one primary and one secondary failure, while five were triple failures, each involving one primary and two secondary failures. With one exception, every set of simultaneous failures involved a line. Apparatus failures that were involved include three generator armatures, four transformers, three reactors, three oil switches, and two bus structures.

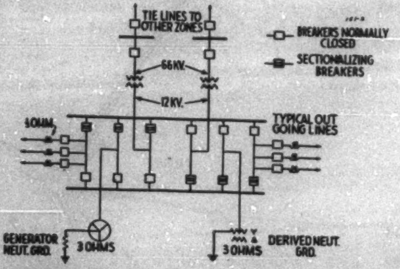

Figure 2. 12-kv station bus diagram

During the period under consideration there were 1,240 primary failures on the Chicago 12-kv systems. Of these failures, 4.35 per cent caused simultaneous failures to occur, thus increasing the total number of 12-kv system failures by 4.84 per cent.

An especially interesting group of simultaneous failures, which occurred in the Northwest zone, is illustrated on figure 1. The primary failure, which was in all probability *B* phase at the location indicated, originated a transient overvoltage on *A* and *C* phases that caused four distinct additional failures and left a record on *A* and *C* phases at both of the spark-gap installations in the Northwest zone. The gaps were set at three times normal voltage. This case nicely illustrates the fact that surges are confined to those parts of the system that are metallically connected to the point of surge origin.

Simultaneous failures may be divided into four types based on the time lag existing between the inception of the primary and secondary failure. These are:

1. Secondary failure occurs within one or two cycles of the primary failure's inception, i.e., simultaneous with the initial surge caused by the primary failure.

2. Secondary failure occurs during the steady-state fault period of the primary failure.

3. Secondary failure occurs simultaneous with the clearing of the primary failure.

4. Secondary failure occurs a definite length of time after the clearing of the primary failure.

No oscillograph records of type 3 failures have been obtained in Chicago. It is reasonable to assume, however, that such failures are possible, and so this type has been included. Most simultaneous failures appear to be of type 1. This is inferred from the fact that the oscillograph records usually show both failures existing at the start of the record, the start being about 0.1 second (six cycles) after the inception of the primary failure. Many records of this type have been obtained. Type 2 failures are fairly common, while type 4 failures are rather rare. Type 2 is illustrated by the oscillogram in figure 7. On this record, a *B*-phase-to-ground cable fault, located three miles from the station, existed from *P* to *Q*. *B*-phase voltage is depressed while *A* and *C* voltages are above normal. At *Q* the secondary fault occurred on *C* phase to ground in another cable one-fourth mile from the station. For three cycles, *Q* to *R*, both faults existed simultaneously. At *R*, the primary fault cleared, leaving the *C*-phase fault on the system. A few records of type 4 simultaneous failures have been obtained on the 12-kv system, but unfortunately these records are not suitable for reproduction. An entirely similar case is, however, available from the records of the 9-kv 25-cycle system and is shown in figure 8. The primary fault was on *A* phase, *S* to *T*. This fault cleared at *T* and the system was normal

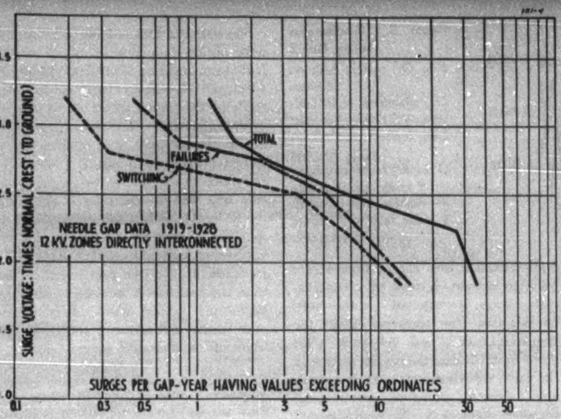

Figure 4. Surge data for 12-kv system, 1919–28

for 1.6 seconds, T to U. At U, the secondary fault occurred on B phase to ground, continuing to V, at which point it was cleared from the system. This interesting record clearly shows that a very definite time lag may occur between the period during which insulation is overstressed and the actual time of its electrical breakdown.

Staged Tests

It is easier to grasp the significance of the test data if the postulated theory of surge production is first understood. The discussion will be confined to surges caused by single line-to-ground faults, which are the highest occurring on the Chicago 12-kv system. The overvoltage resulting from the fault may properly be considered in three parts, as follows.

A. The "Make" Transient

If the initiation of the fault is a simple "make" operation involving no intermittent arcing, then on the approximation that all circuit elements are linear the effect is precisely as though the fault were replaced by a single-phase voltage generator of zero impedance, generating a cancellation voltage that is at all times exactly equal and opposite to the unfaulted steady-state voltage at the fault. The actual voltages and currents in all parts of the network may be obtained by superposing on the unfaulted steady-state condition the transient and ensuring steady state of the network as fed by the cancellation generator.

Figure 9 shows a schematic three-phase diagram of the 12-kv system at a generating station. There are n outgoing lines, each equipped with one-half-ohm reactors. The simplification of zero interphase coupling is introduced and the n conductors and reactors on each phase are grouped to give single parallel equivalents.

A fault is applied on C phase of one of the lines. The cancellation voltage, which may be thought of as a traveling wave if the fault is fairly remote from the station, travels into the station, where it initiates a complex transient whose frequencies are determined mainly by the inductance of the faulted line's reactor and the total system capacitance to ground. Let E be the normal phase-to-ground peak voltage. The theoretical limiting value for the cancellation transient at the bus, assuming infinite neutral impedance, is $4E$ if there are no outgoing lines other than the faulted line, and $2E$ if there are a large number of outgoing lines. This latter value is reduced slightly by the presence of a neutral grounding impedance of a few ohms, the reduction being greater with a resistance ground than with an inductance ground. In any case, the transient resulting from the incoming wave appears almost symmetrically on all three phases of the system. The resulting system overvoltage is the superposition of this cancellation wave and the normal steady state. It is reasonable to expect that for the Chicago

Figure 5. Surge data for 12-kv system, 1932–38

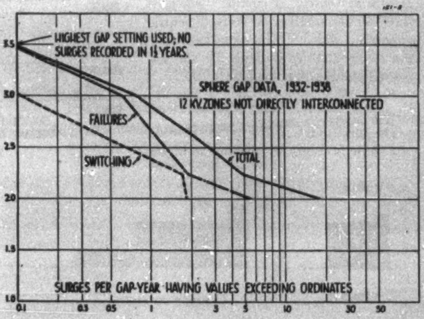

Figure 6 (below). Correlation of surges and failures

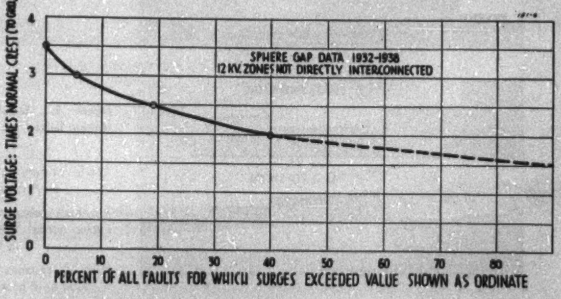

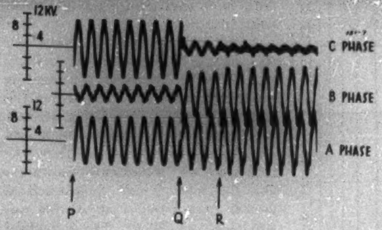

Figure 7. Simultaneous failure, type 2

P to *Q*: primary fault on *B* phase

Q: secondary fault initiated on *C* phase of another line; *B*-phase fault still on first line

Q to *R*: faults coexisting on *B* phase and *C* phase

R: *B*-phase fault cleared; *C*-phase fault still on but cleared later

system this surge, which constitutes the first portion or "make" transient of the system overvoltage, should not exceed 3.5*E*. This value is obtained by adding a maximum expected cancellation transient of 2.5*E* to the normal steady-state value of *E*.

B. The Steady-State Fault Condition

After the transient of the applied cancellation wave has died out, the network conditions may be pictured as the sum of the normal steady state and the steady state of the cancellation generator. More simply, however, the conditions are obtained directly by the methods of symmetrical components. It is easily verified that for Chicago conditions with generator neutral grounding, which is three ohms resistive, or derived neutral grounding, which is three ohms inductive, the steady-state overvoltage on the unfaulted phases will not exceed $\sqrt{3}E$.

C. The "Break" Transient

The surge that results from the clearing of a fault is obtained precisely as in the fault initiation case except that a cancellation current, instead of a cancellation voltage, is "injected" at the fault. In this case, the transient effects the transition from a peak voltage of $\sqrt{3}E$ down to *E* whereas the reverse is true in the fault initiation case. It is reasonable to expect, therefore, greater total transient voltages on the fault "make" than on the break, assuming in all cases no restriking of the arc.

Some complete records of 12-kv surges were obtained in a series of 15 staged fault tests made at Northwest station in Chicago. The faults were thrown directly on the system, which was in normal everyday service. In each of the tests, a line-to-ground fault was applied by a special breaker to *A* phase of one outgoing line on the line side of the one-half-ohm line reactor. In some of the tests the 12-kv station bus was sectionalized to split the Northwest zone 12-kv system into two entirely independent parts (refer to figure 2). In the remainder of the tests the two busses were tied, which is the normal system setup. Four cycles prior to the application of the fault, the following oscillographs were initiated:

1. Cathode-ray oscillograph capacitatively coupled to *C* phase of the 12-kv station bus. Since the faults were applied on *A* phase, the transient overvoltages would appear on *C* and *B* phases. A film speed of six inches per cycle was used.

Figure 9. Cancellation wave on 12-kv system

2. Magnetic oscillograph to record *A*, *B*, and *C* phase potentials on both sections of the 12-kv station bus.

3. Magnetic oscillograph to record the current in the system neutral and *A*-phase fault current.

The *C*-phase potentials recorded by the cathode-ray oscillograph in two of the tests are shown in figure 10. The *A*-phase fault in these two cases consisted of a one-inch arc in air between copper bars. Eight cycles after the initiation of the faults they were cleared by the line breaker. Under each of the *C*-phase potential records, there is entered the cancellation potential, which starts at the time of fault and is equal and opposite to the normal potential on *A* phase. The transient resulting from the application of the cancellation wave is seen to last about one cycle. The first portion of the transient, corresponding to the first half cycle of the natural frequency of this transient, is seen to correlate, as it should,

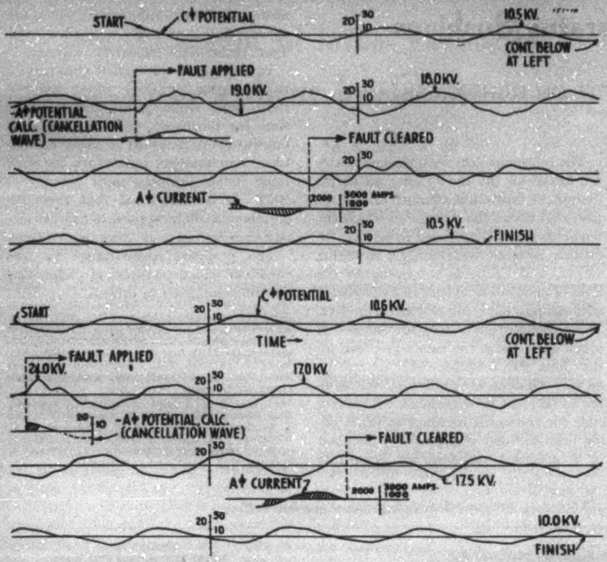

Figure 10. Oscillograms of staged fault tests

a (above)—12-kv zone sectionalized
b (below)—12-kv zone not sectionalized

exactly in both magnitude and polarity with the cancellation potential at the time of fault.

For the test in figure 10*a* the 12-kv bus was sectionalized, resulting in a higher transient frequency than in 10*b* where the systems were tied. The transient frequency did not exceed 500 cycles per second in any of the tests. The absence of higher frequencies, for the detection of which the cathode-ray oscillograph was well adapted, checks the conclusion derived from the spark-gap studies.

The overvoltage during the steady state of the fault is seen to be very close to $\sqrt{3}E$ as expected.

The transient overvoltage accompanying the clearing of the fault was less than $\sqrt{3}E$ in both cases shown in figure 10. Intermittent arcing is not indicated by any of the records obtained. The fault current during the break period is indicated under both oscillograms of figure 10. As is to be expected, the break occurred near a current zero.

The results of the remaining 13 fault tests are in accordance with the two cases described. In no case did the break transient give voltages in excess of $\sqrt{3}E$ and in no case was the faulted steady-state overvoltage in excess of $\sqrt{3}E$. In 5 of the 15 tests a surge voltage of between 24 and 26 kv ($2.27E$ to $2.45E$) was measured within one cycle of the initiation of the fault. In all of these cases the grounding was of the derived neutral type. In four tests with generator (resistance) grounding, the maximum surge potential did not exceed $2E$.

Summary

The highest transient overvoltages on the Chicago 12-kv system occur at the inception of single line-to-ground faults. They may be thought of as resulting from the superposition of a "cancellation wave" on the normal steady-state voltage of the system. The transient is not a high-frequency phenomenon and is not generated by an "intermittent-arcing" mechanism. The maximum crest values reached are in the neighborhood of $3.5E$ and persist for only the first cycle or two of the fault. For the remainder of the fault, including the clearance switching, the maximum overvoltage is $\sqrt{3}E$. These overvoltages may cause secondary (simultaneous) failures in any part of the connected system where the insulation is unable to withstand them for the short times they persist.

Report on Apparatus Bushings

AIEE JOINT COMMITTEE ON BUSHINGS

THE AIEE joint committee on bushings presented a report at the 1940 winter convention in which the committee proposed uniform requirements for the electrical characteristics of outdoor apparatus bushings. Since that time the committee has continued its work and has now completed a tabulation of proposed requirements for indoor and outdoor apparatus bushings rated 2,500 volts and higher.

The scope of the committee includes bushings for circuit breakers, transformers, regulators, and similar apparatus. It does not include wall and roof bushings potheads, and insulators for back-connected disconnecting switches.

The recommendations of the committee are based on the theory that an ample margin of insulation strength should be provided above the voltage to which the bushings may be subjected in service, including dynamic overvoltages, switching surges, and lightning surges up to the level of protection which can be provided with modern lightning protective devices. The impulse characteristics suggested are in accord with the values proposed by the joint AIEE-EEI-NEMA committee on co-ordination of insulation. All tests are to be made in accordance with a test code for apparatus bushings which is being prepared and which will be included in a proposed standard for apparatus bushings. The recommended values are expressed in terms of "withstand voltages" rather than "flashover voltages."

In order to avoid conflict with certain small indoor bushings which will not meet these requirements and to allow time for modifying the design of such bushings it is proposed to delay making these requirements mandatory for such small indoor bushings until January 1, 1943. It is understood that these requirements will be applied to any new design or redesigns made prior to that time.

The proposed requirements for the electrical characteristics of apparatus bushings are given in table I.

Paper 41-76, recommended by the AIEE committees on protective devices, electrical machinery, and power transmission and distribution, and presented at the AIEE winter convention, Philadelphia, Pa., January 27–31, 1941. Manuscript submitted November 18, 1940; made available for preprinting December 18, 1940.

NOTES: [a] Bushings of a given insulation classification are in general recommended for apparatus having a rating up to and including the insulation classification of the bushing and may be used for apparatus of a higher voltage rating when adequate for the particular application.

[b] All values are withstand test values without negative tolerance.

[c] Wet test values are not assigned to indoor bushings.

[d] Either positive or negative waves may be used—whichever gives the lower value.

[e] Bushings for use in large apparatus are those intended for use in transformers rated above 500 kva, outdoor circuit breakers, and other apparatus of corresponding importance.

[f] Bushings for use in small apparatus are those intended for use in transformers rated 500 kva and less and other apparatus of corresponding importance.

[g] Bushings for use in indoor apparatus are those intended for use in indoor-type circuit breakers, instrument transformers, and other indoor apparatus except dry-type instrument transformers, air-cooled transformers, air-cooled regulators, and bushings used primarily for mechanical protection of insulated cable leads.

[h] Bushings for small indoor apparatus may be supplied to withstand a low-frequency test of 38 kv and an impulse test of 95 kv.

The Detection of Initial Failure in High-Voltage Insulation

J. B. WHITEHEAD

M. R. SHAW, JR.
ASSOCIATE AIEE

Introduction

IN a series of accelerated life tests[1] on laboratory samples of impregnated-paper insulation of the type commonly used in high-voltage cables, certain methods have been employed for limiting the breakdown current and thereby the attendant burning of the insulation. In this way it has been found possible to obtain partial failures in which the breakdown is limited to only a portion of the insulation wall, say one-half or one-third of the total number of layers, the remaining layers being apparently unaffected. In these partial failures, the burning is very slight and it is possible to obtain a very good idea as to the location of the initial point of failure and the nature of its subsequent progress. With one of the methods used it has been possible on occasion to limit the breakdown to only two layers of paper and to study the extension of the failure through adjacent layers. The method gives great promise for the study of the mechanism of breakdown under laboratory conditions. In this paper we are reporting some of the preliminary results of a more extended program of study still under way.

Probably the condition most conducive to the beginnings of failure under normal conditions of service is the presence of gas bubbles, pockets, or layers within the body of the insulation. Potential gradients at which ionization can begin in such gas pockets or layers are often exceeded in equipment for only moderately high voltages. Gas layers in the insulation circuit may be caused by imperfect impregnation, or as the result of bending or other mechanical strains in the normal processes of manufacture, transportation, and installation. In other cases gas spaces may result from the temperature variations attendant upon load changes. The accelerated life tests already referred to have indicated still a further cause of gas liberation, namely high-voltage stress on the oil layers or other free oil in impregnated-paper insulation, such as the channels between successive turns of paper tape. Study of the partial failures referred to clearly indicates that initial failure usually starts in the oil channel and is accompanied by the evolution of gas.

Under alternating stress gaseous ionization and other initial discharges occur first on the crests of the alternate half waves. This gives the discharges an impulse character so that in conjunction with the capacitance and inductance of the high-voltage circuit the discharges take on an oscillatory character. This fact has afforded a simple means of detecting the presence of such discharges and has been utilized almost exclusively by those who have studied the phenomenon.

Ripples on the crests of a-c voltage waves due to gas discharges were apparently first shown by Edward Bennett,[2] using the electromagnetic oscillograph. With the development of the cathode-ray oscilloscope, visual observation of the ripples is a simple matter, and this instrument is commonly used as a qualitative detector in all studies of this character. The earlier studies of Paine[3] and coworkers are well known. The possibility of more sensitive and quantitative studies has been shown by Arman and Starr,[4] the distinguishing characteristic of whose work is a bridge, filter, and amplifier circuit free from disturbance due to local discharges in the high-voltage circuit and extraneous to the specimen under study.

Measuring Equipment

In the present work the method of Arman and Starr, with certain modifications and extensions, has been used for the detection of initial internal gaseous discharge and the quantitative study of the subsequent stages of the discharge, first on impregnated-paper insulation originally containing no free gas, and also on several types of insulating wall with gas pockets and oil channels of controlled dimensions.

BRIDGES

Two types of bridge have been used. The first for voltages up to 30 kv was the modified Schering bridge due to Whitehead.[5] This bridge was in constant use for the measurement of power factor in the series of accelerated life studies on impregnated-paper insulation of cable type already referred to. At regular intervals in the life runs of these specimens the detection circuit of the present research was connected to the Schering bridge, following the periodic measurement of 60-cycle power factor in the life runs. In this way it was possible to fix within a few hours the time at which internal ionization began and in some measure to correlate the progress of internal ionization with changes in 60-cycle power factor and applied voltage.

For closer study of internal discharges, it appeared desirable to work with thinner specimens in which the critical gradients would be reached with the specimen continuously in the bridge circuit. Accordingly the simplified form of Schering bridge shown in figure 1 was constructed. C_x is the specimen and C_a is the air capacitor. Auxiliary studies indicated that up to ten kilovolts, the limit of bridge operation, the high-voltage circuit including the air capacitor was free from internal discharges.

BRIDGE TRANSFORMER

The detection equipment was connected to either of the bridges through a high-quality bridge transformer, with electrostatic shielding between the pri-

Paper 41-27, recommended by the AIEE committee on power transmission and distribution, and presented at the AIEE winter convention, Philadelphia, Pa., January 27–31, 1941. Manuscript submitted July 30, 1940; made available for preprinting December 4, 1940.

J. B. WHITEHEAD is professor of electrical engineering and director of the school of engineering at The Johns Hopkins University, Baltimore, Md. M. R. SHAW, JR., affiliated with The Johns Hopkins University at the time this paper was written, is now with the Corning Glass Works, Corning, N. Y.

[1] For all numbered references, see list at end of paper.

mary and secondary windings, both of which were capacitively balanced with respect to ground. This permitted one end of the output winding of the transformer to be grounded without disturbing the symmetry of the bridge circuit. This is important because it permits the grounding of one side of the whole amplifying and detecting circuit, thereby permitting that the whole circuit be enclosed in a grounded shield. Circuit changes on the output side of the transformer thus have no influence on the balance of the bridge. The voltage ratio of the transformer was measured between 1 and 50 kilocycles and found to be closely uniform up to about seven kilocycles, and to decrease somewhat beyond. The over-all impedance ratio of the transformer based on its turn ratio was 4.4 to 1 which brought about an impedance match between the bridge and the high-pass filter.

FILTER

A filter having three full sections was adopted. The cutoff frequency, 3,600 cycles, was chosen because it was low enough to pass the band of oscillations due to internal discharges and high enough to reject any high harmonics of the 60-cycle charging current. The terminal impedance at each end was 5,500 ohms. Impedance matching at the input end of the filter was accomplished by the bridge output transformer. Impedance matching with the amplifier was effected by placing a noninductive resistor of 5,500 ohms across the filter.

AMPLIFIER

A resistance-capacitance coupled amplifier was inserted between the filter and the detector (see figure 1). Details of the amplifier are shown in figure 2 with circuit constants given. At 10,000 cycles, the frequency at which all calibrations were made, the amplification factor was 4,700. As a function of the input voltage saturation took place at an input voltage of 5.5 millivolts. Consequently all readings recorded were obtained with input voltage to the amplifier of five millivolts or less.

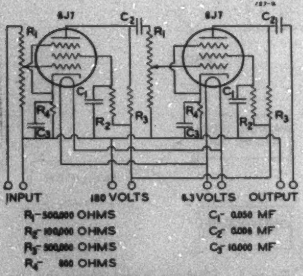

Figure 2. Amplifier

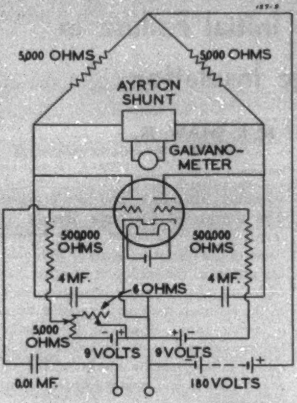

Figure 3. Circuit diagram of balanced vacuum tube voltmeter using type 6N7 tube

DETECTORS

A standard model of a well-known make of cathode-ray oscilloscope was used for qualitative measurements. An amplifier of gain 40 was incorporated in the oscilloscope. This, in conjunction with the external amplifier made it possible to realize an over-all gain of 40×4,700, or 188,000 at 10,000 cycles. This instrument is extremely useful, permitting ready and rapid visual observation of conditions obtaining in the circuit.

For quantitative measurements a balanced vacuum tube voltmeter as indicated in figure 3 was used. This arrangement is independent of small changes of battery voltage and the combination of duplex tube, decade resistance boxes, and Ayrton shunt for the galvanometer, results in a very sensitive quantitative instrument. The calibration of the meter with galvanometer of 120 megohms sensitivity with various settings of the shunt was found to hold over the range 60 cycles to 50 kilocycles. The voltage required for one centimeter deflection at maximum sensitivity was 13,000 microvolts. The over-all amplification factor between the input of the bridge transformer and the output of the amplifier as function of frequency may be had from the data in table I. At ten kilocycles the over-all amplification factor was 1,830. Hence a voltage of 13,000/1,830 or 7.1 microvolts gave a galvanometer deflection of one centimeter. In figure 4 the voltage for one centimeter deflection is plotted over the range 1 to 50 kilocycles.

Tests and Calibration of Equipment

TEN-KILOVOLT DISCHARGE DETECTION BRIDGE

A first necessary step in the use of this method is to balance the bridge for minimum effect in the detection apparatus, of local high-frequency discharges external to the specimen itself. Accordingly a small discharge gap consisting of a few layers of varnished cambric between two brass electrodes was connected between the bridge and the high side of the supply transformer, as shown in figure 1. The primary voltage is increased until discharge occurs in the gap, the latter being adjusted for discharge at relatively low voltage. The detecting circuit is then connected using the oscilloscope as indicator. The bridge is then balanced so as to bring to a minimum the signal on the screen of the oscilloscope. This minimum could be made practically zero, even though the ionization in the gap was strong enough to be audible several feet away.

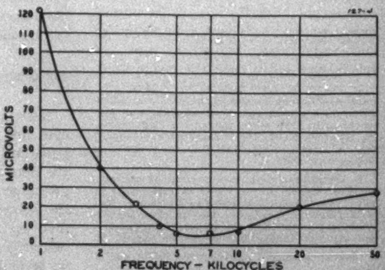

Figure 4. Voltage necessary at bridge terminals to cause one centimeter galvanometer deflection

In this method it is to be noted that stress is applied to the specimen under test at 60 cycles but that only a fraction of the total discharge current over a comparatively narrow band of frequencies reaches the detecting circuit. This fraction passes through the several elements of the complete circuit before reaching the final detecting instrument. It seemed advisable, therefore, to test the over-all sensitivity and accuracy of the equipment by comparison with the known properties of the breakdown strength of air in thin layers as related to pressure, through Paschen's law. The apparatus was a guarded capacitor consisting of a layer of air backed by a layer of glass for preventing complete breakdown. For the range of pressure between 15 centimeters and 76 centimeters Hg, the voltage stresses for initial ionization, as determined by the equipment, and as computed from Paschen's law are shown in figure 5 for the temperatures indicated. In figure 6, the critical stress as a function of the electrode spacing is shown in the solid curve; for comparison, the experimental results of Dubsky[6] on thin air films, are also plotted.

30-Kv Schering Bridge

The large physical size of this bridge resulted in enough pickup of extraneous high-frequency disturbance to serve as a guide in the preliminary balance without recourse to a discharge gap. The effect of the external discharges was readily balanced out by adjustment of the resistance arms and the variable capacitor. In this condition the bridge could be used for the study of initial discharges in specimens of impregnated-paper cable insulation on life test and at higher voltage gradients in these life specimens than possible with the ten-kilovolt bridge.

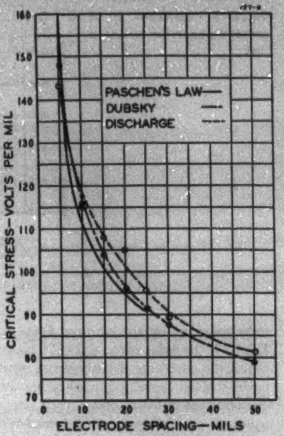

Figure 6. Critical stress for gaseous discharge between parallel plates as detected by discharge bridge and as function of separation of plates

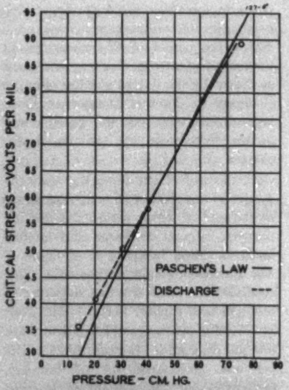

Figure 5. Critical stress for gaseous discharge between parallel plates as detected by discharge bridge and as function of pressure

Experimental Results

The method was applied to several types of insulation as follows: (*A*) laboratory specimens of impregnated paper as found in high-voltage cables, and originally free from gas bubbles or pockets; (*B*) single oil channels as found in cable insulation; (*C*) channels and bubbles of air of known dimensions, and subject to visual observation. The general method of test was the determination of the voltage gradient at which internal gaseous discharge begins and the increase in the "volume" of the latter with increasing gradient. At an early point it was found that the elapsed time of application of stress may have an important influence on both the critical discharge stress and on the "volume" of discharge at sustained high stress. The readings of the detecting instrument are obviously proportional to an integrated value of a product of the number of discharge areas and the intensity of discharge current in each area. In what follows the word "volume" has been used to indicate this integrated product.

(A). Cable Insulation

In the accelerated life tests on standard types of impregnated-paper insulation, the test samples consisted of 16 layers of 0.005-inch wood pulp paper one inch wide, spiraled cable fashion on one-inch diameter smooth brass tubes with $33^{1}/_{3}$ per cent overlay and a butt spacing of approximately $^{1}/_{64}$ inch. These samples were dried and impregnated with a low-viscosity high-grade cable oil in the usual way, and tested to break down under the impregnating oil. The accelerated step-up life test started at an average stress of 400 volts per mil on the specimen and the applied stress was increased by 3.12 per cent every four hours, thus giving a geometric increase such as to bring the stress to 700 volts per mil within three days. Under this program, the life of the specimen was from 60 to 80 hours, and the breakdown gradients from 600 to 800 volts per mil, at 50 to 65 kv on the test transformer.[1]

At four-hour intervals the life test was interrupted for the measurement of power factor over the range 100 to 400 volts per mil. Following the power-factor measurement, the galvanometer was cut out of

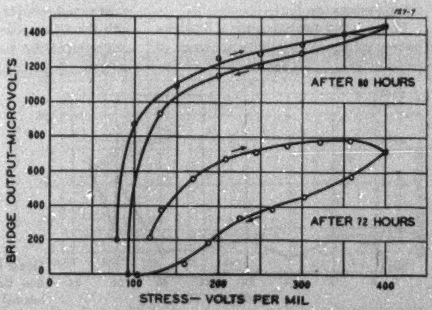

Figure 7. Ionization in impregnated-paper insulation

the Schering bridge and the discharge equipment connected. The bridge was then balanced for a negligible minimum reading of the discharge equipment due to external discharges in the high-voltage wiring, up to a voltage somewhat below that at which internal discharges begin in the sample. The equipment was then ready for observation.

First observation was made on the specimen after it had been on test for 24 hours reaching a stress of 467 volts per mil. No internal discharge was found at this point nor at subsequent intervals of 12 hours up to 60 hours with a final stress of 618 volts per mil. Positive readings of internal discharge were first observed after the specimen had been on test for 72 hours with a final stress of 679 volts per mil. In these observations it is to be recalled that the specimen was removed from the life test voltage, power factor and internal discharge being measured over the range 100 to 400 volts per mil.

The relation between internal discharge and stress, finally found after 72 hours of test, is shown in the lower curve of figure 7. As will be seen the volume of discharge increases with the stress, tending, however, to a maximum value and then to a somewhat lower value at the maximum stress of 400 volts per mil. The volume of discharge on decreasing stress is seen to be markedly lower than for increasing stress In another test, the stress was held constant at 400 volts per mil and it was found that the volume of discharge decreased with time and ultimately ceased entirely. This indicates that when internal discharge occurs, it will continue at substantially lower values of applied stress. However, there is a lower value of stress at which there will be a decrease and final disappearance of the volume of internal discharge. This decrease is probably due to gas absorption and oil sealing, or perhaps to internal burning or carbonization, short-circuiting the gas spaces involved.

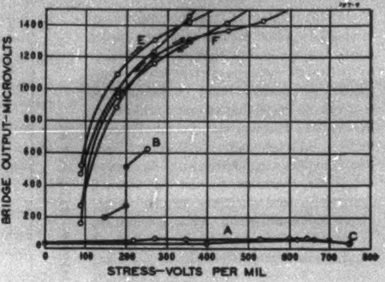
Power-factor measurements at 60 cycles corresponding to the above sequence of tests are given on the curve of figure 8. Point 7 is the value at the end of 72 hours before the discharge measurements were made. After sustained application at 400 volts per mil with cessation of internal discharge, the specimen was put back on high-voltage life test for one hour, then removed, and tested again for power factor and internal discharge. The power-factor value is given at point 8 and there was no evidence of internal discharge. The specimen was then returned to life test for eight hours with a final stress of 722 volts per mil, and during this interval two power-factor readings indicated the increase shown beyond point 8 in figure 8. The internal discharge now followed the upper curve of figure 7, which has the same general shape but greater magnitude than the earlier curve. The influence of time is still present though not so marked. It appears probable that owing to the higher stress, deterioration and new internal discharges are increasing more rapidly than the decreases shown in the tests at lower stress. On return to life test after these measurements, the specimen failed within two hours.

In order to be independent of the above life tests and to reach higher stresses at lower over-all voltage, similar specimens with only half the thickness of wall, were constructed, impregnated, and tested with the 30-kv Schering bridge. In this arrangement the stress could be carried to 800 volts per mil and internal discharge measurements made at all stresses up to this figure without interruption.

The specimen was first carried slowly up to 700 volts per mil with the result shown in curve *A* of figure 9. The level of discharge due to external influence is seen to be very low and uniform in the whole range of stress. After 12 hours rest, the power-factor stress relation shown by curve *A* of figure 10 was taken. The increase in power factor thus found seems to indicate that internal discharges are taking place in the specimen. None such were found however until after ten minutes' application of the maximum stress of 700 volts per mil, at which point a violent indication of internal discharge was found. The voltage was immediately removed and the specimen given a ten-minute rest. It was then found that internal discharge started at 100 volts per mil, with a further increase as indicated by curve *B* of figure 9. A power-factor observation taken at this point indicated an increase of value, and during the period of this measurement the volume of internal discharge increased as shown by the dotted portion of curve *B*, figure 9. Further increase of stress beyond 200 volts per mil gave a still further increase in the volume of discharge.

At the end of the foregoing test, the specimen was given a 70-hour rest period at the end of which period the relation between internal discharge and applied stress is shown in curve *C* of figure 9. The specimen is apparently in the same condition as when it was first subjected to test, perhaps slightly better. One hour at 700 volts per mil gave no indication of internal discharge. Increase to 750 volts per mil, maintained for 55 minutes, brought about the renewal of internal discharge. The voltage was immediately reduced to zero and then gradually reapplied, discharge beginning at 620 volts

Figure 9. Ionization in impregnated-paper half-wall specimen



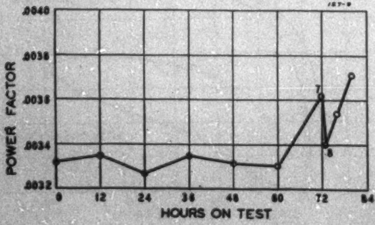


Figure 8. Power-factor variation before and after initial internal discharge

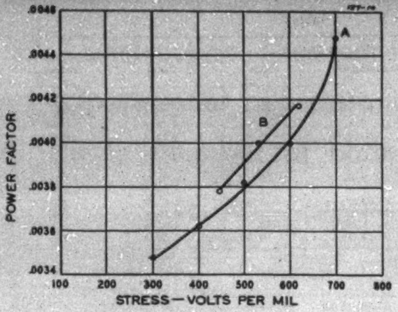

Figure 10. Power factor of half-wall specimen

per mil. The power factor had also increased (see curve *B* of figure 10).

Two discharge stress runs were then made, with a short-time interval between runs. The results are shown in curves *E* and *F* of figure 9. Note that the volume of discharge in the second run was less than in the first, suggesting a slight recovery in the interval between runs.

After another 12-hour rest period, the specimen was again found to be free of internal discharge after 700 volts per mil, maintained for eight hours. The stress was then increased to 750 volts per mil when internal discharge began immediately, but the specimen failed before a quantitative measurement could be taken.

(B). Oil Channels in Small Specimens

In order to investigate the value of stress at which internal discharges begin in an oil channel in impregnated paper, a group of two- and three-layer impregnated-paper specimens were prepared and tested between horizontal, parallel, polished brass plates. The three-layer specimens consisted of two sheets of impregnated paper and a third sheet in which a slit was made. In the two-layer specimens, one layer was continuous and the other contained a slit. The slits were the same width (0.0156 inch) as the oil channels in the life test specimen referred to above; their length was three inches. Drying and impregnation were in accordance with three-layer and two-layer specimens referred to above.

Preliminary tests were made with three-layer and two-layer specimens of continuous sheets of paper, and it was found that these could be carried to 1,100 and to 1,200 volts per mil respectively, and maintained for six hours without evidence of internal discharge.

For testing the specimens containing slit papers forming oil channels, the following schedule was used: (*a*) 15 minutes at 1,000 volts per mil in the oil channel (ratio of dielectric constants, impregnated paper to oil: 2); (*b*) three per cent per minute increase in stress to 1,600 volts per mil in channel; (*c*) five per cent increase in stress at five-minute intervals from 1,600 volts per mil to incipient failure.

This accelerated schedule is necessary to eliminate the influence of time found in the earlier studies. In two two-layer specimens, initial internal discharge was found at 1,530 and at 1,860 volts per mil in the oil channel; in the three-layer specimens the values found were 1,600 and 1,630 volts per mil. These values are somewhat higher than those reported by Whitehead[1] which were in the range 1,350 to 1,550 volts per mil. In the latter case, however, the specimens were under high stress a much longer time. In the present case all of the incipient discharges eventually produced punctures originating in the oil channel.

(C). Tests on Air Bubbles in Oil Channels

A special test cell permitted the insertion of air bubbles in the oil channel in a slit in impregnated paper. Visual observation was possible through the upper electrode, consisting of a salt solution in a tray with plate glass bottom. Special provisions permitted the operation of the cell up to ten kilovolts without disturbance in the detecting circuit due to discharges from the guard circuit.

With paper in place, the whole apparatus was evacuated to one millimeter Hg at 40 degrees centigrade for two hours, at which point all gas has ceased to come out of the oil. A test was then made at low stress which showed the absence of discharges. The upper electrode was then carefully moved to one side, exposing the channel. An air bubble was then introduced by means of an eye dropper, and the electrode then brought back into place.

The gaseous discharge as a function of applied stress was measured on bubbles of lengths, 47.2, 98.5, and 132 mils, and width of 15.6 mils. The quantitative results for bubbles of the same length varied somewhat but certain characteristics were invariably repeated. Three curves, for temperature 40 degrees centigrade are shown in figure 11. For shorter bubbles, the discharge in general increases with increasing stress and decreases with decreasing stress. For the longer bubbles the conditions become erratic and no definite behavior is indicated which may be correlated with the results on the cable specimens. Using the results on the shorter bubbles as a measure, it is suggested that the initial discharges in the cable specimens begin bubbles less than 0.1 inch in length, and 0.03 inch in width.

Discussion

The peculiar relationships between internal discharge, stress, and time noted in connection with the cable specimens may perhaps be best explained in terms of the frequent observation that first evidences of breakdown occur in the oil

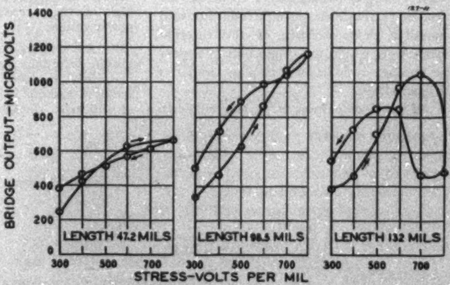

Figure 11. Ionization in air bubbles

Table I

Frequency (Kilocycles)	Loss or Gain* (Decibels)				Amplification Factor
	Amplifier	Transformer	Filter	Total

*+ indicates a gain; − indicates a loss.

channels and that the initial stages of this breakdown are accompanied by the liberation of gas. At initial discharge in the oil, corona formation results in the evolution of gas and polymerization. Once a bubble of gas is formed, it may be ionized at a value of stress much lower than that causing the original discharge. The gas bubble, however, is not stable and may be reabsorbed into the oil. This is responsible for the variation with time of the intensity or volume of discharge, and also for the complete recovery following a long rest period. The healing effect of time without stress is particularly noticeable in the thicker cable specimens on life test at higher stresses. Interruption of the high stress and subsequent measurement of power factor at very much lower stress provides opportunity for healing action due to gas absorption. It also probably accounts for the steady decrease of internal discharge even when stress is applied to the specimen, when this stress is substantially lower than that at which the internal discharge was first initiated.

The peculiar loops showing decreases of volume of discharge with increasing stress and vice versa noticed in the impregnated paper and air bubble tests may perhaps be explained as due to variations in pressure in gas pockets. A more or less rapid increase in pressure causing a reduction in the volume of discharge is followed by a slow release of pressure with corresponding increase in the volume of discharge.

The increase in the strength of the insulation with successive discharge cycles may possibly be explained by the process of polymerization. The wax which replaces the oil has high dielectric strength and prevents this particular spot from ionizing again. With increasing stress, discharge will first occur at a different point. It also appears possible that surface discharges, tree patterns, and the like, may at times result in the short circuit of a gas pocket, thus reducing the ionizing stress and causing a reduction and possible disappearance of the internal discharge, which may then only reappear in another cycle in another place, and at a higher stress.

Of particular interest is the evidence that the time of application of stress is an important factor in fixing the value of stress at which discharge appears; for example in the thin-wall cable specimens, the stress was taken up to 700 volts per mil without immediate evidence of discharge. Moreover at this high value of stress a considerable time was required before internal discharge appeared.

The tests on oil channels indicate that for short times the strength of these channels is quite high and probably very close to that of the oil alone. The lower values reported by Whitehead show the influence of time due perhaps, as suggested by him, to contact with the paper. The peculiar results found in the observation on air bubbles may perhaps be due to temperature, to saturation conditions in the gas, or to subsequent changes in volume or pressure in the gas. Further study is in progress, notably as to the time element, both under stress, and after its removal.

Conclusions

(1). Internal discharges occur in impregnated-paper insulation well in advance of failure and once initiated continue at stresses much below the breakdown values commonly attributed to this type of insulation.

The stresses at which initial discharges begin in insulation originally free of gas bubbles are from seven to eight times as high as the stresses usually obtaining in power cables.

(2). An improved method for detecting initial internal discharges in insulating materials is described. Calibrated in terms of gaseous ionization in thin air films of different thicknesses and at different pressures, it is found to detect initial discharge and its variation in accordance with Paschen's law.

(3). The seat of incipient failure in the samples of impregnated-paper insulation here studied is the oil channel between successive turns of paper tape. An initial discharge is followed by the evolution of gas which is ionized on successive alternating wave crests; the resulting oscillations are utilized for detecting the initial discharge and as a measure of the subsequent volume of discharge.

(4). Specimens stressed to the point where initial discharge begins may be brought back to apparently normal condition by allowing them to stand without stress for a period of time. This is attributed to the absorption of gas by the oil.

(5). A plus or minus variation with time under stress below the critical value, may occur in the volume of internal discharge. This is attributed to changes in pressure, or in volume of ionized gas, or to the absorption of gas by the oil.

A Construction Theorem for Evaluating Operational Expressions Having a Finite Number of Different Roots

PAUL C. CROMWELL
ASSOCIATE AIEE

IN the course of the past 25 years Heaviside's direct operational method of solving differential equations has, to a large extent, been replaced by solutions involving functional transformations. While mathematically sound this trend has resulted in placing a powerful analytical tool far above the mathematical equipment of the average engineer. With the exception of the celebrated expansion theorem or the method of partial fractions no *direct* method appears to have been discovered by which the average engineer or engineering student could solve even relatively simple differential equations by Heaviside's calculus. Several expansion theorems have been developed[1,2,3,4] to cover cases where repeated roots are present but none of these have been set up in a form which could be used by undergraduates. It does not appear that any direct general procedure has ever been suggested to cover the usual type of asymptotic solutions which appear in problems in electrical engineering.

It is the purpose of this paper to develop a direct method for evaluating operational expressions involving a finite number of different roots. For rational expressions the theory is based upon the usual procedure in obtaining the particular integrals of ordinary differential equations with constant coefficients. The procedure is heuristically extended to irrational operators by analogy so that its greatest utility lies in the field of asymptotic solutions.

The term "construction" has been applied to this theorem because the operations to be performed are only indicated as contrasted with the general solutions which characterize the "expansion type" theorems.

In order that this paper may be of value to engineers who are not familiar with integration in the complex plane no mathematically rigorous proof will be given. An outline for such a proof is presented in the last section.

Definitions and Fundamental Operations

Consider the steps necessary in solving for the particular integral of an ordinary linear differential equation with constant coefficients. As an example take the equation

$$(D+a)i=\epsilon^{bt}t \tag{1}$$

where D is defined as the usual derivative operator of differential equations d/dt and t is the independent variable time. i is the dependent variable and is usually the current in amperes for electrical work. a and b are constants and $b>-a$. To solve for the steady-state current, or particular integral, divide both sides of the equation by $(D+a)$

$$i_s=\frac{1}{(D+a)}\epsilon^{bt}t \tag{2}$$

The exponential can now be "shifted" from right to left.

$$i_s=\epsilon^{bt}\frac{1}{(D+a+b)}t \tag{3}$$

The next step is to expand the denominator in ascending powers of D by division or by the binomial theorem

$$i_s=\frac{\epsilon^{bt}}{a+b}\left(1-\frac{D}{(a+b)}+\frac{D^2}{(a+b)^2}\cdots\right)t \tag{4}$$

Performing the operations indicated

$$i_s=\frac{\epsilon^{bt}}{a+b}\left(t-\frac{1}{a+b}\right) \tag{5}$$

which is the steady-state solution for equation 1 Notice that no arbitrary constants appear and that the process involves differentiation but no integration. This is important since the usual Heaviside operator p can be substituted in place of D. $1/p$ is to mean $\int_0^t dt$. In order to identify this general process a new operator will be defined.

Definition of a Bar Operator: Two bars placed over an operator $\overline{\overline{(p+a)}}^n$ *are to indicate the complete operation of expanding the operator in ascending powers of p by the binomial theorem and performing the indicated differentiations. n may be a positive or negative real number including fractions. If this operator operates on a linear combination of powers of t multiplied by an exponential the first operation is always a "shift" of the exponential.*

By the use of the bar operator the result shown in equation 5 can be expressed as

$$i_s=\overline{\overline{(p+a)}}^{-1}\epsilon^{bt}t \tag{6}$$

Notice that equation 6 without the double bar might be confused with the equivalent complete operational solution which would include a transient term not indicated by (6).

These bar operators have several properties which are of interest when used with the fundamental and well-known operational expression

$$\frac{p}{(p+a)^n}1=\frac{\epsilon^{-at}t^{n-1}}{\Gamma(n)} \tag{7}$$

n may be a positive integer, proper or improper fraction and a is a constant, real or complex. These properties are easily proved so that no proof will be given here.

1. Bar operators are commutative. That is, they may be used in any order to bring about the same result.

$$\overline{\overline{(p+b)}}^m\,\overline{\overline{(p+c)}}^r\left[\frac{\epsilon^{-at}}{\Gamma(n)}t^{n-1}\right]=\overline{\overline{(p+c)}}^r\,\overline{\overline{(p+b)}}^m\left[\frac{\epsilon^{-at}}{\Gamma(n)}t^{n-1}\right] \tag{8}$$

Where $a\neq b\neq c$ and r and m are positive.

2. Reciprocal bar operators perform reciprocal operations.

$$\overline{\overline{(p+b)}}^n\left[\overline{\overline{(p+b)}}^{-n}\frac{\epsilon^{-at}}{\Gamma(n)}t^{n-1}\right]=\frac{\epsilon^{-at}}{\Gamma(n)}t^{n-1} \tag{9}$$

3. In the case of "equal roots"

$$\overline{\overline{(p+a)}}^m\left[\frac{\epsilon^{-at}}{\Gamma(n)}t^{n-1}\right]=\frac{\epsilon^{-at}t^{n-m-1}}{\Gamma(n-m)} \tag{10}$$

m and n are both positive integers or fractions. If $(n-m)$ is a negative integer or zero the gamma function of this number is infinite and the result is zero.

4. The case of unequal roots

$$\overline{\overline{(p+b)}}^m\left[\frac{\epsilon^{-at}}{\Gamma(n)}t^{n-1}\right]=\epsilon^{-at}(b-a)^m\overline{\overline{\left(1+\frac{p}{b-a}\right)}}^m\frac{t^{n-1}}{\Gamma(n)} \tag{11}$$

Paper 41-37, recommended by the AIEE committee on basic sciences, and presented at the AIEE winter convention, Philadelphia, Pa., January 27-31, 1941. Manuscript submitted June 16, 1939; made available for preprinting December 10, 1940.

PAUL C. CROMWELL is assistant professor of electrical engineering, college of engineering, New York University, New York, N. Y.

The author wishes to express his appreciation to Professor Kurt O. Friedrichs of the mathematics department, New York University, to whom he is deeply indebted for many valuable criticisms and suggestions during the preparation of this paper. Also to Professor Ernst Weber, electrical engineering department, Polytechnic Institute of Brooklyn, for his helpful suggestions and interest in the project.

n is positive but m may be positive, negative, or a fraction. $a \neq b$.

5. If $b=0$ and $n=1$ in case 4 the result is

$$\overline{(p)}^{m}\epsilon^{-at}=(-a)^{m}\epsilon^{-at} \tag{12}$$

For integral positive powers of m the bar operator behaves as an ordinary differential operator. If m is a fraction or has a negative value, however, the results are not the same as for the equivalent operational procedure. Purely imaginary terms obtained in this way must be set equal to zero after the final result has been obtained.

Since the bar operators behave in exactly the same manner for fractional values of n as for integral values a "fractional power" differential equation may be set up as easily as an "integral power" differential equation. As an example

$$\overline{(p+a)}^{1/2}i=\epsilon^{bt}t \tag{13}$$

and the steady-state solution is, as in equation 6

$$i_s=\overline{(p+a)}^{-1/2}\epsilon^{bt}t \tag{14}$$

It should be pointed out that these "fractional power" differential equations have been set up by analogy with "integral power" differential equations; a purely formal procedure.

Operational Differential Equations

An operational differential equation is to be defined for use in this paper as any one of the equivalent "fractional" or integral power differential equations which may be set up from an operational expression such as

$$i=\frac{p}{(p+a_1)^{n_1}(p+a_2)^{n_2}(p+a_3)^{n_3}\ldots(p+a_k)^{n_k}}1 \tag{15}$$

No loss in generality will result in the following theory if only three roots are considered since the process may obviously be extended to cover any number of roots. Consider the operational expression

$$i=\frac{p}{(p+a_1)^{n_1}(p+a_2)^{n_2}(p+a_3)^{n_3}}1 \tag{16}$$

Using the operator in the numerator in turn with each of the root functions in the denominator to form an expression corresponding to equation 7 the three most easily recognizable operational differential equations are

$$\overline{(p+a_2)}^{n_2}\overline{(p+a_3)}^{n_3}i=\frac{\epsilon^{-a_1t}t^{n_1-1}}{\Gamma(n_1)} \tag{17a}$$

$$\overline{(p+a_1)}^{n_1}\overline{(p+a_3)}^{n_3}i=\frac{\epsilon^{-a_2t}t^{n_2-1}}{\Gamma(n_2)} \tag{17b}$$

$$\overline{(p+a_1)}^{n_1}\overline{(p+a_2)}^{n_2}i=\frac{\epsilon^{-a_3t}t^{n_3-1}}{\Gamma(n_3)} \tag{17c}$$

The only restrictions are that $a_1 \neq a_2 \neq a_3$ and n_1, n_2, and n_3 are positive integers, proper or improper fractions. Notice that if the n's are positive integers the bars could be removed from the bar operators on the left-hand sides of equations 17 since they would then be ordinary differential equations any one of which could be represented operationally by (16).

It is now to be proved that in the case of integral positive values of n the unique solution for equations 17 consists of the sum of the particular integrals of (17*a*), (17*b*), and (17*c*). Actually these operations may be extended to fractional values of n but the proof to be given here is not mathematically rigorous. In this case the result usually includes an asymptotic series.

The following expression for $i(t)$ will satisfy equations 17.

$$\begin{aligned}i=&\frac{1}{(p+a_2)^{n_2}(p+a_3)^{n_3}}\frac{\epsilon^{-a_1t}t^{n_1-1}}{\Gamma(n_1)}+\\&\frac{1}{(p+a_1)^{n_1}(p+a_3)^{n_3}}\frac{\epsilon^{-a_2t}t^{n_2-1}}{\Gamma(n_2)}+\\&\frac{1}{(p+a_1)^{n_1}(p+a_2)^{n_2}}\frac{\epsilon^{-a_3t}t^{n_3-1}}{\Gamma(n_3)}\end{aligned} \tag{18}$$

since when (18) is substituted back into, say (17*a*)

$$\begin{aligned}&\overline{(p+a_2)}^{n_2}\overline{(p+a_3)}^{n_3}\times\\&\quad\left[\frac{1}{(p+a_2)^{n_2}(p+a_3)^{n_3}}\frac{\epsilon^{-a_1t}t^{n_1-1}}{\Gamma(n_1)}\right]+\\&\overline{(p+a_2)}^{n_2}\overline{(p+a_3)}^{n_3}\times\\&\quad\left[\frac{1}{(p+a_1)^{n_1}(p+a_3)^{n_3}}\frac{\epsilon^{-a_2t}t^{n_2-1}}{\Gamma(n_2)}\right]+\\&\overline{(p+a_2)}^{n_2}\overline{(p+a_3)}^{n_3}\times\\&\quad\left[\frac{1}{(p+a_1)^{n_1}(p+a_2)^{n_2}}\frac{\epsilon^{-a_3t}t^{n_3-1}}{\Gamma(n_3)}\right]=\\&\qquad\qquad\frac{\epsilon^{-a_1t}t^{n_1-1}}{\Gamma(n_1)}\end{aligned} \tag{19}$$

The first term of (19) gives the same time function by (9) while the next two terms become zero since they involve expressions having "equal roots" as in (10). Equivalent results are obtained if (18) is substituted in equations 17*b* and 17*c*. That is, the solution (18) satisfies each of the operational differential equations 17*a*, 17*b*, and 17*c*. In terms of ordinary differential equation theory the first unit of (18) is the particular integral of (17*a*) and the second and third units together form the complementary function with constants of integration already evaluated. Thus the particular integral of one of the equations 17 forms a part of the complementary function for each of the other equations. Since the three original equations are known to have identical operational solutions equation 18 is always a unique evaluation of the operational expression (16). If the n's are positive integers the result (18) is always in a closed form. If (18) is extended to fractional values of n the result usually contains one or more asymptotic series.

The Construction Theorem

The process outlined in the last section can obviously be extended to cover any expression of the form (15) so that the equivalent time function would be given by:

$$i=\sum_{i=1}^{k}\frac{1}{\prod\limits_{j=1\ j\neq i}^{k}(p+a_j)^{n_j}}\frac{\epsilon^{-a_it}t^{n_i-1}}{\Gamma(n_i)} \tag{20}$$

The denominator of the bar operator of (20) is the same as that of (15) except that $(p+a_i)^{n_i}$ is omitted.

If the original operational expression (15) had a constant in the numerator instead of the operator p equation 20 would represent the solution for $pi(t)$. The final solution for $i(t)$ could be easily obtained, except in the case where (20) represents an asymptotic series, by operating on the result with p^{-1}. If the original expression had a numerator $F(p)$ consisting of a polynomial in integral powers of p equation 20 could be operated on with $F(p)$ to give the new solution. The integration must be performed before the differentiations or the net result of dividing $F(p)$ by p applied to equation 20.

The result may be given in the form of a "construction theorem" to evaluate operational expressions.

$$\begin{aligned}&\frac{F(p)}{\prod\limits_{i=1}^{k}(p+a_i)^{n_i}}1=\frac{F(p)}{p}\times\\&\quad\left[\sum_{i=1}^{k}\frac{1}{\prod\limits_{j=1\ j\neq i}^{k}(p+a_j)^{n_j}}\frac{\epsilon^{-a_it}t^{n_i-1}}{\Gamma(n_i)}\right]\end{aligned} \tag{21}$$

The restrictions for using this theorem are:

1. Functions having equal roots must be combined so that no two roots are identical including zero. The roots may be real or complex. (Two roots which are the same except for the sign are different roots.)

2. $F(p)$ is a polynomial containing only constants or constants multiplied by integral positive powers of p. In cases where the network is impulsive $F(p)$ will contain higher powers of p than the denominator. The result will not, in general, contain the impulsive terms which may be obtained in the usual manner.[8]

3. n_i is a positive integer, positive or negative proper or improper fraction.

4. In cases where the final result contains purely imaginary terms (as, for instance, in the case of $\sqrt{p}\epsilon^{-at} = \sqrt{-a}\epsilon^{-at}$ it is necessary to specify that such terms be dropped after all operations have been performed.

5. The theorem cannot be used in this from when $F(p)/p$ would operate on such terms as t^m where $m \leqq -1$. This restriction is necessary to prevent the "integration" of an asymptotic series.

The construction theorem in this form is more useful than the more complete form to be given which removes the last restriction. An operational expression which contains a fractional power root function in the numerator can usually be cleared of such terms by the usual algebraic procedure.

The last restriction may be removed by writing the left-hand side of equation 21 so as to segregate the zero root function. If $a_k = 0$ and $n_k = q$ then

$$\frac{F(p)}{p^q \prod_{i=1}^{k-1}(p+a_i)^{n_i}} 1 =$$

$$F(p)\left[\frac{p}{p^{q+1}\prod_{i=1}^{k-1}(p+a_i)^{n_i}}\right]1 =$$

$$F(p)\left\{\sum_{i=1}^{k-1}\frac{1}{p^{q+1}\prod_{j=1,\, j\neq i}^{k-1}(p+a_j)^{n_j}}\frac{\epsilon^{-a_i t}t^{n_i-1}}{\Gamma(n_i)} + \frac{1}{\prod_{i=1}^{k-1}(p+a_i)^{n_i}}\frac{t^q}{\Gamma(q+1)}\right\} \quad (22)$$

q is a positive integer or fraction. In this case $a_i \neq 0$. Multiplying both numerator and denominator by p arranges the expression inside the square brackets in the form of equation 15 so that the solution is given by the last line which is equivalent to equation 21. This final form of the construction theorem appears to be perfectly general under the limitations imposed by the first four restrictions. Only differentiations are involved which may be performed on any time function which may appear.

Illustrative Example

Evaluate the operational expression

$$i = \frac{p+c}{(p+a)(p+b)} 1 \quad (23)$$

Using the first form of the construction theorem (21) $F(p) = p+c$ and (23) can be written

$$i = \left[\frac{p+c}{p}\right]\left[\frac{p}{(p+a)(p+b)} 1\right] \quad (24a)$$

Two of the fundamental forms (7) may be recognized in (24*a*)

$$i = \left[1+\frac{c}{p}\right]\left[\frac{1}{(p+b)}\left\{\frac{p}{(p+a)} 1\right\} + \frac{1}{(p+a)}\left\{\frac{p}{(p+b)} 1\right\}\right] \quad (24b)$$

From (7)

$$\frac{p}{(p+a)} 1 = \epsilon^{-at}$$

and

$$\frac{p}{(p+b)} 1 = \epsilon^{-bt}$$

and (24*b*) becomes

$$i = \left[1+\frac{c}{p}\right]\left[\frac{1}{(p+b)}\epsilon^{-at} + \frac{1}{(p+a)}\epsilon^{-bt}\right] \quad (24c)$$

Shifting the exponentials

$$i = \left[1+\frac{c}{p}\right]\left[\epsilon^{-at}\frac{1}{b-a} + \epsilon^{-bt}\frac{1}{a-b}\right] \quad (24d)$$

Performing the integration and rearranging the final result is

$$i = \frac{c}{ab} + \frac{1}{b-a}\left[\left(\frac{a-c}{a}\right)\epsilon^{-at} + \left(\frac{c-b}{b}\right)\epsilon^{-bt}\right] \quad (24e)$$

Cable With Terminal Inductance

One of the interesting problems originally solved by Heaviside[6] is the case of a unit voltage applied to an infinite cable with terminal inductance. The operational expression giving the voltage at the head end of the cable is of the form

$$V_0 = \frac{1}{1+(bp)^{3/2}} 1 \quad (25)$$

where b is a positive constant. Write this as

$$V_0 = \frac{1-(bp)^{3/2}}{1-(bp)^3} 1$$

$$= \frac{1}{b^3}\left\{b^{3/2}p \times \left[\frac{p}{\sqrt{p}\left(p-\frac{1}{b}\right)\left(p+\frac{1-j\sqrt{3}}{2b}\right)\left(p+\frac{1+j\sqrt{3}}{2b}\right)}\right] - \frac{1}{p} \times \left[\frac{p}{\left(p-\frac{1}{b}\right)\left(p+\frac{1-j\sqrt{3}}{2b}\right)\left(p+\frac{1+j\sqrt{3}}{2b}\right)}\right]\right\} 1 \quad (26)$$

The construction theorem may now be used for both terms.

$$V_0 = b^{3/2}\left[\frac{p}{\sqrt{p}\left(p-\frac{1}{b}\right)\left(p+\frac{1-j\sqrt{3}}{2b}\right)} \times \epsilon^{-\left(\frac{1+j\sqrt{3}}{2b}\right)t} + \frac{p}{\sqrt{p}\left(p-\frac{1}{b}\right)\left(p+\frac{1+j\sqrt{3}}{2b}\right)}\epsilon^{-\left(\frac{1-j\sqrt{3}}{2b}\right)t} + \frac{p}{\sqrt{p}\left(p+\frac{1+j\sqrt{3}}{2b}\right)\left(p+\frac{1-j\sqrt{3}}{2b}\right)}\epsilon^{\frac{1}{b}t}\right] - \frac{b^{3/2}}{1-(bp)^3}\left\{-\frac{1}{2\sqrt{\pi}}t^{-3/2}\right\} - \frac{1}{b^3 p}\left[\frac{1}{\left(p-\frac{1}{b}\right)\left(p+\frac{1-j\sqrt{3}}{2b}\right)}\epsilon^{-\left(\frac{1+j\sqrt{3}}{2b}\right)t} + \frac{1}{\left(p-\frac{1}{b}\right)\left(p+\frac{1+j\sqrt{3}}{2b}\right)}\epsilon^{-\left(\frac{1-j\sqrt{3}}{2b}\right)t} + \frac{1}{\left(p+\frac{1+j\sqrt{3}}{2b}\right)\left(p+\frac{1-j\sqrt{3}}{2b}\right)}\epsilon^{\frac{1}{b}t}\right] \quad (27)$$

When the indicated operations of (27) are carried through and the terms collected

$$V_0 = 1 - \frac{4}{3}\epsilon^{-\frac{1}{2b}t}\cos\frac{\sqrt{3}t}{2b} + \frac{1}{2\sqrt{\pi}}\left(\frac{b}{t}\right)^{3/2} \times \left[1 - 1\cdot3\cdot5\cdot7\left(\frac{b}{2t}\right)^3 + 1\cdot3\cdot5\cdot7\cdot9\cdot11\cdot13\left(\frac{b}{2t}\right)^6 \ldots\ldots\right] \quad (28)$$

The final result[5] as given by equation 28 checks that of Heaviside obtained by "advanced ideas" not stated.

This example is sometimes given as a case in which "Heaviside's method" fails, although he obtained the correct solution. As Heaviside himself made no general statement of his methods it might be inferred that he was at least partially aware of the relationship between his own work and ordinary differential equations. He makes the statement that,[7] "sometimes a series of differentiations may equivalently replace a series of integrations." It is unfortunate that he did not develop this relationship more fully.

Sinusoidal Electromotive Force Applied to an Infinite Cable

Another well-known problem is to find the entering current when a sinusoidal electromotive force is applied to an infinite cable. The operational equation is of the form

$$i = \sqrt{p}\,\sin\omega t 1 \quad (29)$$

which is a combination of

$$\sqrt{p}\,1=\frac{1}{\sqrt{\pi t}}$$

and

$$\frac{\omega p}{p^2+\omega^2}1=\sin\omega t$$

Using the construction theorem

$$i=\omega p\left[\frac{1}{\sqrt{p}\,(p-j\omega)}\epsilon^{-j\omega t}+\frac{1}{\sqrt{p}\,(p+j\omega)}\epsilon^{-j\omega t}+\frac{1}{\omega^2+p^2}\frac{1}{\sqrt{\pi t}}\right] \qquad (30)$$

and the final result is:

$$i=\sqrt{\frac{\omega}{2}}(\sin\omega t+\cos\omega t)-\frac{1}{\sqrt{\pi t}}\left(\frac{1}{(2\omega t)}-\frac{1\cdot3\cdot5}{(2\omega t)^3}+\frac{1\cdot3\cdot5\cdot7\cdot9}{(2\omega t)^5}\cdots\right) \qquad (31)$$

One of the advantages of using this method of attack on operational expressions is the ease of checking the result obtained. Equation 29 may be set up in two equivalent operational differential equations:

$$(p^2+\omega^2)i=\frac{\omega p^2}{\sqrt{p}}1=-\frac{\omega}{2\sqrt{\pi}}t^{-3/2} \qquad (32)$$

and

$$\sqrt{p}\,i=\frac{\omega p^2}{p^2+\omega^2}1=\omega\cos\omega t \qquad (33)$$

If (31) is substituted in (32) the first term of (31) becomes zero since the second derivative of this term is the term itself multiplied by $-\omega^2$. All of the series terms will cancel out except the term on the right of (32). If (31) is substituted in (33) the first term of (31) becomes $\omega\cos\omega t$ and the odd-half power terms of (31) are reduced to zero as in equation 10.

Conclusions

The construction theorem which has been developed is not always the most direct method of solving every operational expression for which it is applicable. In the case of fractional power root functions the result will, in general, contain one or more asymptotic series. In particular if a certain solution is desired in terms of a convergent series of fractional powers of the variable t the result must be obtained by some other method. Several of the more obvious advantages in using the theorem may be listed as follows:

(*a*). The theorem brings out the relationship between ordinary differential equations and Heaviside's calculus. This results in the concept of "equivalent operational differential equations" which is far more important than the development of a fixed routine for the solution of individual operational expressions.

(*b*). The theorem involves no exceptions or complicated tests which must be applied before it is used.

(*c*). The necessary mathematical manipulations are easily learned since the main prerequisites are a knowledge of the binomial theorem and the ability to differentiate simple functions of time.

(*d*). Operational expressions which might otherwise be evaluated by Heaviside's expansion theorem can, more often than not, be evaluated by inspection.

(*e*). The final result may be easily checked by substituting results into the original equations.

Outline for a Rigorous Mathematical Proof of the Construction Theorem

To prove the construction theorem it is necessary and sufficient to show that the operations indicated by the key equation 18 can be substantiated by an equivalent procedure using the Bromwich[8] contour integral in the complex plane (*a*) for integral positive values of n and (*b*) for fractional positive values of n.

The symbols and definitions to be used in this discussion are given by reference 8.

Equation 16 becomes

$$i=\frac{1}{2\pi j}\int_{-j\infty+c}^{+j\infty+c}\times\frac{\epsilon^{zt}}{(z+a_1)^{n_1}(z+a_2)^{n_2}(z+a_3)^{n_3}}dz \qquad (34)$$

1. Bromwich contour integral 1 is equivalent to Bromwich contour integral 2 for (34) since for large values of z the finite values of a may be set equal to zero and the proof is given by reference 8, pages 58–61.

2. The final result for (34) can now be obtained by taking the sum of the contributions of the individual roots along Bromwich integral 2. To evaluate the contribution of one root, say $-a_1$, first change the variable to $z'=z+a_1$. This is equivalent to the shifting operation indicated for ϵ^{-a_1t} in equation 18. Expand the bracket terms containing a_2 and a_3 by the binomial theorem in ascending powers of z' separately and then perform the indicated multiplications. The resulting series is analytic for values of z' less than the least radius of convergence of the two original series but not for large values of z'.

The contribution of each root is now in the form of a series of terms of the type

$$\frac{\epsilon^{-a_1t}}{2\pi j}\int_{Br_1}\frac{\epsilon^{z't}}{z'^{r+1}}dz'=\frac{\epsilon^{-a_1t}t^r}{\Gamma(1+r)} \qquad (35)$$

good for all values of r. Proof for (35) is indicated on pages 76–8 of reference 8. Term by term this can be shown to be equivalent to the differentiating process indicated by the first unit of equation 18.

4. In the case of integral positive values of n the contribution of the two straight lines of Bromwich integral 2 for any particular root in an expression such as (34) is zero, so that (35) includes only the integral around the circle whose radius can be made as small as necessary to make the series expansion convergent. For integral powers of n equation 18 always gives the evaluation of expression 16 in closed form.

5. In the case of fractional powers of n the series expansions do not represent the original functions beyond the least radius of convergence of the two series. The expression to be integrated along the straight lines of Bromwich integral 2 does not converge except close to the new origin. However, for large values of t most of the integral is obtained in the neighborhood of the origin, a process which usually results in an asymptotic series.

In integrating along Bromwich integral 2 for fractional powers of n it sometimes happens that one root appears in the "tail" of the integration path for the other. In this case the weaker root may be dropped for an asymptotic solution. This is equivalent to the restriction 4 for the construction theorem. The contributions obtained in this way coincide with those given by the construction theorem.

A Study of Sound Levels of Transformers

H. FAHNOE
ASSOCIATE AIEE

I. Introduction

MUCH has been accomplished in the past few years in understanding the problem of transformer noise. It has been definitely established that magnetostriction discovered by Joule in 1842 is the principal source of transformer noise. The various harmonic vibrations generated in the core by magnetostriction have been analyzed. Methods of calculating sound levels in terms of the standards prepared by the American Standards Association have been developed. A large number of modes in which different core structures may vibrate have been determined experimentally and analytically. As a result, methods for determining the correct design proportions of the core have been developed so that the natural modes of vibration may not coincide with the harmonic vibrations generated by magnetostriction. These methods have been successfully applied to actual designs of transformers including the largest ratings.

This paper will serve as a partial report of the research and experimental work which has been accomplished in the laboratories of the company with which the writer is associated.

II. Transformer Noise

Until recent years it had been assumed generally that the main cause of transformer noise was the magnetic pull between the laminations at their joints. In order to determine the correctness of this assumption, an investigation was started in 1932 by experimenting with an iron ring without gaps or joints. This ring was made up of laminations, 18 inches outside diameter, 8½ inches inside diameter, built up to five inches. The laminations were clamped between heavy maple blocks; they could be energized by means of one turn through the center opening of the ring or more turns wound uniformly around the ring. When energized with alternating current, the ring emitted the characteristic "hum" heard from any transformer as soon as it is energized. The "hum" or noise increased as the flux density was increased. With a sine wave of voltage applied to the exciting winding and with a fixed number of ampere turns, the noise level was the same whether the ring was energized by means of one or several turns.

From these tests it was apparent that the joints in the core and mechanical dissymmetries between the energizing winding and the core could not account for the noise emitted from a well-built transformer.

In measuring the vibrations parallel with the plane of the laminations at different points around the periphery of the ring, it was found that the ring as a whole expanded with a very pronounced vibration of twice the applied frequency. These peripheral vibrations were all in phase or, in other words, the diameter of the ring was pulsating with an amplitude which was found to depend upon the flux density in the ring. It was only possible to explain these vibrations as a phenomenon of magnetostriction. The unit elongations calculated from these vibrations were of the expected order based on a knowledge of the magnetostriction.

Typical vibration measurements at the fundamental vibrational frequency taken on a rectangular core are shown in figure 1. It will be noticed that the deflections at the different flux densities are approximately proportional to the length of the various core members. The deflections shown occur simultaneously, that is, they are in phase. Vibrations as symmetrical as shown in figure 1[1] are obtained only when the laminations are straight and uniformly clamped. By changing the method of clamping, the deflections along a certain member may change considerably. The core may, for instance, vibrate as shown in figure 2.

The 120-cycle sound intensities calculated from the deflections shown in figures 1 and 2 correspond closely to those measured with a sound level meter with the microphone located approximately one-half inch from the core. The 120-cycle sound level of this core is, therefore, practically entirely accounted for by magnetostriction. The relation between magnetostriction and induction (B) is generally such that the core vibrates also at harmonically related higher frequencies. Both odd and even harmonic vibrations are produced. In figure 3 is shown such vibrations measured at one end of a large rectangular core. With the apparatus available, it was possible to measure vibrations up to the tenth harmonic. In this figure the vibrations are plotted as velocities. The amplitudes of the vibrations are in inverse ratio to the frequencies.

The number and magnitude of these higher harmonic vibrations depend upon the nature of the steel, the flux density, and the linear dimensions of the core. Any particular grade of steel has, therefore, a characteristic noise spectrum for each flux density. Such a spectrum is shown in figure 4 for steel at a flux density $B=15{,}000$ gausses. The ordinates are plotted in decibels.

The core of any transformer is in itself a structure which may vibrate in many modes, depending upon its degree of freedom. When the laminations of a core as shown in figure 1 are clamped between heavy end frames, the core is practically free to swing only in a direction parallel with the plane of the laminations. A large number of modes of vibration are possible in this plane, each mode occurring at a certain frequency. This form of core and end frame construction is common in shell-type transformers. If the core is not clamped between heavy end frames and is standing upright as in core-type transformers, it has several degrees of freedom, that is, it may vibrate in several planes, and in numerous modes in each plane. In either case, it is possible that the core structure may be in mechanical resonance with one or more of the frequencies generated in the core due to magnetostriction. The amplitudes of vibration at such frequencies will, therefore, be in excess of the forced vibrations caused by magnetostriction.

In figure 5 are shown some typical vibration measurements made on a shell-type transformer which was energized at a constant induction at different frequencies. In this test the core was not clamped tight, and the bottom and top end frames were, therefore, more or less loosely coupled with the core. The vibrations were measured at five points along the vertical center line of the long side as shown.

The upper end frame showed resonance at approximately 100 cycles (figure 5, point 5a); above 130 cycles it was driven

Paper 41-53, recommended by the AIEE committee on electrical machinery, and presented at the AIEE winter convention, Philadelphia, Pa., January 27–31, 1941. Manuscript submitted November 22, 1940; made available for preprinting December 12, 1940.

H. FAHNOE is design engineer for the Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.

The author wishes to thank C. R. Hanna, W. O. Osbon, S. J. Mikina, and J. G. Baker of Westinghouse research laboratories, and H. V. Putman, S. Bennon, and F. J. Vogel of Westinghouse transformer engineering department for the many helpful suggestions received during this investigation.

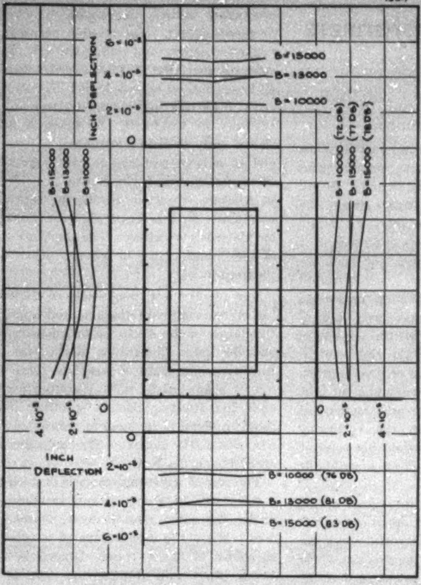

Figure 1. 120-cycle core deflections parallel with the plane of laminations at 60-cycle excitation

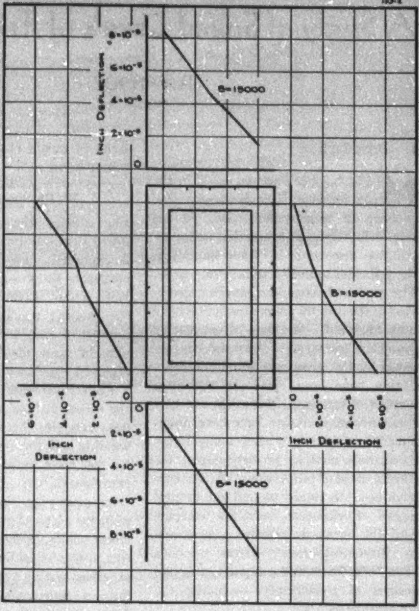

Figure 2. 120-cycle core deflections parallel with the plane of laminations at 60-cycle excitation

by the core which was in resonance at 136 cycles as shown in figure 5 (points 5*b*, 5*c*, and 5*d*). The calculated deflection of the core, due to magnetostriction, was approximately 0.05 mil double amplitude, and it will be noted that at 136 cycles, the core vibrated with an amplitude 16 times that corresponding to the magnetostriction. This means that the noise level on this side of the core was approximately 24 decibels higher than normal at this particular flux density. From figure 5, point 5*e*, it will be seen that the lower end frame is in resonance at approximately 102 cycles and starts to be driven by the core when the frequency was above 132 cycles.

By increasing the coupling between the core and the end frames, that is, by clamping the structures together, the vibrations in the range from 100 to 130 cycles will be somewhat increased. It is, therefore, evident that it is desirable that the core and the end frames have as nearly as possible the same natural frequencies. It will also be noted from these figures, that the band of partial resonance extends about 20 to 25 cycles on either side of the resonance frequency.

The mode of vibration at the resonance frequency of 136 cycles was determined by the use of two equally sensitive vibration pickups connected in series so that their voltages add. The mode was of the nature shown in figure 6*a*. Two of the opposite sides are deflecting outward at the instant the other two sides are deflecting inward. This is the lowest possible mode for a box structure which has practically only one degree of freedom. The exciting frequency of the supply at the 136 cycles vibrational frequency was 68 cycles. The same mode would have occurred at 136 cycles if the core had been energized at 34 cycles. In this case, the core would have been in resonance with the second harmonic vibration due to magnetostriction. But, because of clamping in the core and since for this particular steel the second harmonic driving force is less than for the fundamental, the amplitude of the 136-cycle vibration would have been less.

If the frequency had been further increased above 136 cycles, another resonance point would have occurred at approximately 292 cycles. The mode of vibration at this frequency would have been as shown in figure 6*b*. Here all four sides are simultaneously deflecting outward. This mode requires a rather rigid joint at the corners and is, therefore, not always excited.

At still higher frequencies more complicated modes are excited. The different sides will then vibrate in odd number of half cycles.

Figure 7 shows the consecutive modes of vibration which occur in a three-phase shell-type transformer.

The frequencies of these modes depend upon the dimensions of the core and the modulus of elasticity of the steel used. They may be calculated from a formula of the form

$$f=K\frac{W}{l_1^2} \qquad (1)$$

where

K = a function of the ratio l_1/l_2 and the modulus of elasticity
W = width of the laminations
l_1 = mean length of the longest side
l_2 = mean length of the short side

From experimental data it has been found advisable to design the core of

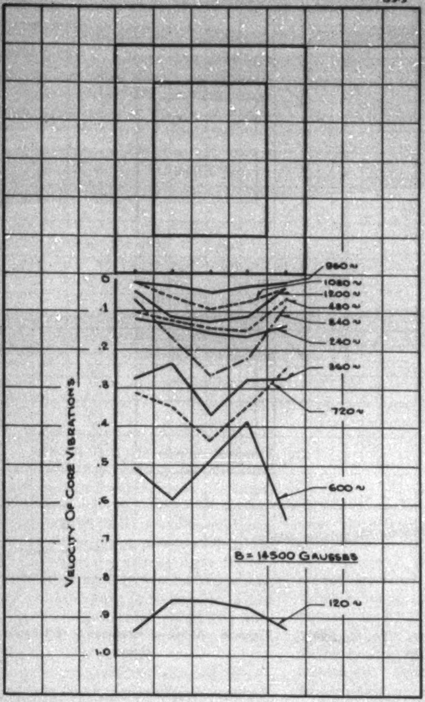

Figure 3. Velocity of core vibrations parallel with the plane of laminations at 60-cycle excitation

such dimensions that its natural frequencies are separated approximately 25 to 30 cycles from any of the harmonic frequencies generated in the core by the excitation frequency.

The end frames for shell-type transformers are more or less complicated box structures and their natural frequencies may be determined along the same lines as indicated for the core.

As previously stated, the core-type transformer as usually constructed is free to vibrate in several planes. The modes of vibration parallel with the plane of the laminations may be of the same nature as the modes described for box structures, and may be determined by means of equation 1. Such a mode for a single-phase core-type transformer is shown in figure 8. In this particular core the mechanical resonance frequency was 294 cycles. This mode would, therefore, not be excited by any of the frequencies generated in the core at 60-cycle excitation. The amplitudes in the center of the legs are approximately 19 times that corresponding to the magnetostriction at this particular flux density. On the other hand, the upright core represents two or more columns with a load at their ends which are free to vibrate in planes principally parallel and perpendicular to the laminations. The core may, therefore, also vibrate in modes as shown in figures 9 and 10, in a plane parallel with the laminations or in modes as shown in figure 11, in a plane perpendicular to the plane of laminations. In figure 11, the elongations of the legs in the direction of their length are restrained by inertia forces due to the presence of large masses on their ends, and they bow out. Some of these modes are rather critical and difficult to duplicate under apparently similar conditions. They are apparently influenced by the mounting of the core on its foundation.

With resonance eliminated, by proper selection of the core dimensions, the amplitude (A) at the fundamental vibrational frequency of any member of the core may be calculated from the magnetostriction characteristics of the steel. For a core member of length (L), the amplitude at each end equals

$$A=\frac{\Delta L}{L}\times\frac{L}{2} \tag{2}$$

where $\Delta L/L$ = elongation per unit length due to magnetostriction. The corresponding physical intensity of the sound wave may be calculated by means of the fundamental equation for a plane sound wave, emitted from a large plane vibrating surface.

The maximum excess pressure in such a wave equals

$$P=V\times d_0\times A\times 2\pi f \tag{3}$$

where V = velocity of wave, d_0 = mean density, A = maximum amplitude of the wave, and f = frequency.

When V is in centimeters per second

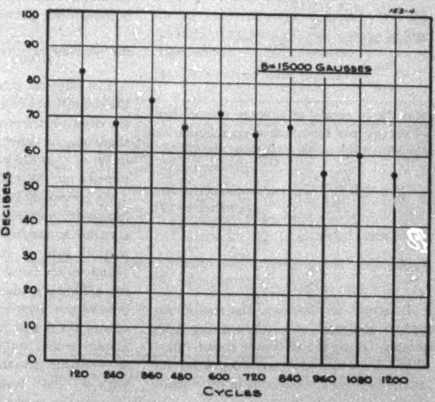

Figure 4. Noise spectrum of transformer steel at 60-cycle excitation

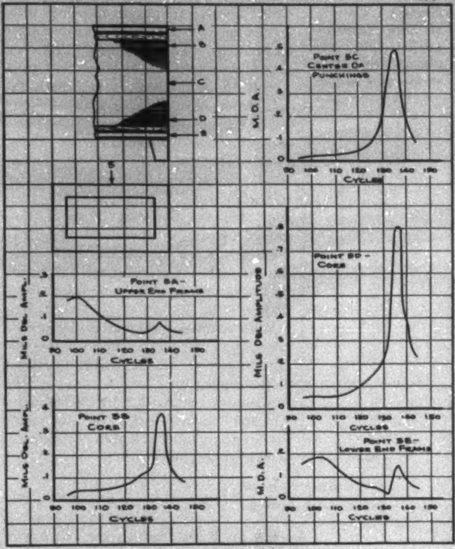

Figure 5. Resonance curve of shell-type transformer core. Core not clamped

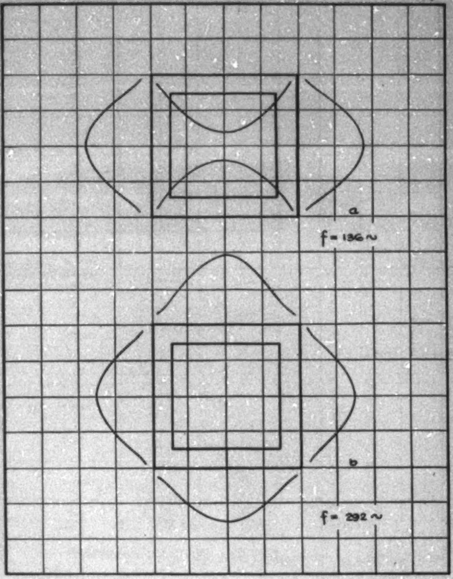

Figure 6. Mode of vibrations of rectangular cores

(=33,300 for air), d_0 in gram per cubic centimeter (=0.0012 for air), the rms excess sound pressure in dynes per square centimeter equals

$$P_{\text{rms}} = 177 \times A_{\text{cm}} \times f \tag{4}$$

or if A is in inches

$$P_{\text{rms}} = 452 \times A_{\text{in}} \times f \tag{5}$$

The average energy density of such an acoustic wave equals

$$W = 2\pi^2 A^2 f^2 d_0 = \frac{P_{\text{rms}}^2}{d_0 V^2} \text{ gram per cubic centimeter} \tag{6}$$

and the intensity or average rate of flow of energy per unit area perpendicular to the direction of propagation, equals

$$I = W \times V = \frac{P_{\text{rms}}^2}{d_0 V} \text{ ergs per second per square centimeter} \tag{7}$$

For a wave in air

$$I = 2.5 \times 10^{-9} \times P_{\text{rms}}^2 \text{ watts per square centimeter} \tag{8}$$

In sound terminology, the decibel expresses the ratio of any given sound intensity (I) to the reference sound intensity. The standard reference level for intensity level comparisons is 10^{-16} watts per square centimeter. The decibel is defined as

$$\text{db} = 10 \log_{10} \frac{I}{10^{-16}} \tag{9}$$

The decibel also expresses the ratio of any given sound level pressure (P) to the reference pressure. The standard reference level for pressure level comparisons is 0.0002 dyne per square centimeter. Since the intensity is proportional to the square of the pressure, we have

$$\text{db} = 20 \log_{10} \frac{P}{0.0002} \tag{10}$$

The physical intensity, in decibels, of the sound wave emitted at the fundamental vibrational frequency of the core may, therefore, be determined by substituting in (9) or (10) the values for I or P determined from (8) or (5).

As previously stated, a large number of harmonic vibrations are produced in the core due to magnetostriction. The arithmetical sum of the intensities, of the sound waves caused by these vibrations, for ordinary grades of silicon steel, is in general not more than one decibel in excess of the sound intensity of the fundamental sound wave. The sound intensity measured with a sound level meter with a "flat" frequency response will, therefore, approximately equal the intensity of the fundamental sound wave calculated as indicated above. This value will be designated as db_F. The intensities of the individual harmonics may also be weighted according to any of the recognized standard equal loudness contours for pure tones. For transformers it is the standard practice to refer all sound level measurements to the 40-decibel equal loudness contour. This value may be measured directly with a modern sound level meter, and will be designated as db_{40}.

The difference between the sound measured with the "flat" and the 40-decibel frequency response will give a fair indication of the quality or the harmonic components of the sound measured. This difference may, therefore, be designated "harmonic index" (h.i.), or

$$\text{h.i.} = \text{db}_F - \text{db}_{40} \tag{11}$$

Where the h.i. is large it is an indication that the sound contains large components of low-frequency tones, whereas a small h.i. indicates that higher frequency tones are predominating.

The harmonic index of a certain grade

of steel as a function of the induction is shown in figure 12.

The sound level of the core may now be estimated as follows. The amplitude of the core vibrations at fundamental vibrational frequency is determined from the magnetostriction of the steel, the length of the magnetic circuit involved, and the flux density at which the core is worked. From this amplitude the excess pressure of the sound wave in dynes per square centimeter and the corresponding decibel sound intensity is calculated (db_p). In order to obtain the sound level corresponding to the 40-decibel frequency response, the "harmonic index" corresponding to the flux density at which the core is worked should be subtracted from the above sound intensity, or the sound level of the core is approximately

$$db = db_p - h.i. \qquad (12)$$

Numerous tests on different cores and at different flux densities have shown close agreement between the calculated and measured sound levels. However, because of the large number of assumptions made in these calculations and since these assumptions are only approximations, caution should be made in their use. The method of calculation would, for instance, have to be changed in case the steel has a sound spectrum widely different from that commonly used in present transformers.

It is well known that the load currents give rise to magnetic forces around and between the high- and low-voltage coils of a transformer. These forces will produce vibrations of the coils with double the applied frequency. Higher harmonics are in general not produced. The construction of the coils is in general such that they are relatively poor sound radiators. In a properly designed transformer, the vibrations produced by the coils will, therefore, contribute relatively little to the total noise level of the transformer when measured on the 40-decibel frequency response.

When the core and coils are placed in their tank and immersed in oil, their motion is transmitted through the oil to the tank wall and from there emitted as sound waves to the surrounding air. For most of the vibrations generated in the core the oil may be considered an incompressible fluid. This means that the oil will act as an added mass to the tank wall and only a small amount of energy at the higher frequencies will be transmitted through the oil and the tank wall as a true wave motion. The tank wall, bottom, and cover are, therefore, forced to vibrate as diaphragms. In general, these diaphragmatic vibrations are not produced in the tank wall as a whole, at any frequency. The tank is a relatively complex structure. Radiators, potheads, switch cabinets, etc., may be welded to the tank wall. Its surface is, therefore, broken up in a large number of smaller areas, vibrating with different phases and magnitudes. Provided no parts of the tank surface are in resonance with any of the exciting frequencies produced by the core, the resulting vibrations are forced. Their magnitudes may be smaller than that of the core. The reduction depends upon the height and thickness of the tank wall, the distance between the core and tank wall, the relative density of the material of the tank wall and that of the oil.

Methods for predetermining the amount of attenuation are being studied, but the problem is very complex and empirical constants are used at present.

Assuming the oil to act as an incompressible fluid, the average "harmonic index" of the tank wall vibrations will correspond closely to the average "harmonic index" observed on the core itself. For example, on one of the largest transformers built, the average "harmonic index" of the core was 9.1 decibels when measured out of its tank. When the transformer was placed in its tank, the average h.i. measured 9.6 decibels, indicating relatively little change in the harmonic vibrations of the core and the tank wall. A large number of similar

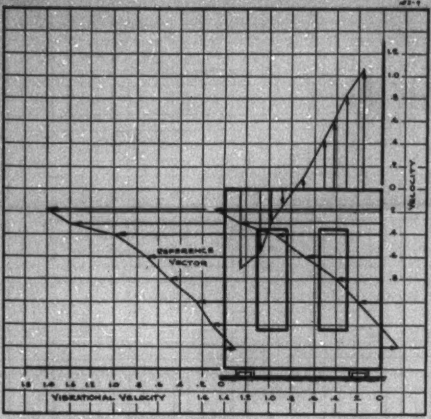

Figure 9. Core vibrations at 124-cycle vibrational frequency in a plane parallel with the laminations of a three-phase core

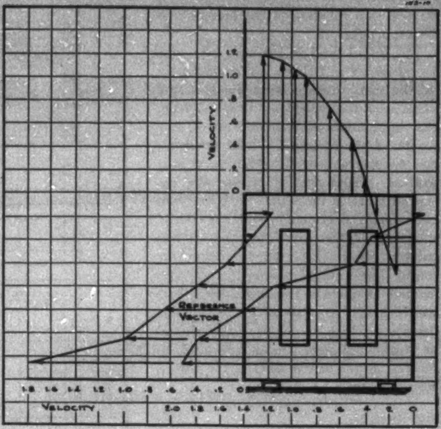

Figure 10. Core vibrations at 116-cycle vibrational frequency in a plane parallel with the laminations of a three-phase core

tests on a variety of transformers have given similar results. Where a large discrepancy has been observed it has been an indication of resonance in some parts of the tank wall or improper mounting of the transformer in its tank. The tank wall or segments of the tank wall may have free vibrations of their own at a large number of frequencies and modes. If such vibrations are in resonance with any of the core vibrations, they may in general be reduced by relatively simple means, such as braces anchored at suitable points.

Cooling tubes, radiators, etc., may complicate the motions of the tank wall, but in themselves these parts are relatively poor sound radiators for sounds of the frequencies involved in transformer operation. They contribute, therefore, relatively little to the total sound level of the transformer.

The vibrations of the tank may produce two kinds of sound, when the transformer is installed in its final location:

1. A direct air-borne sound, radiated from the tank wall, cover, radiators, etc.

2. A sound transmitted through the transformer foundation to the wall or other structural work of the building in or near where the transformer is installed.

Of these two sources, number 1 is, in general, the most important and also the most difficult to insulate against. Air-borne sounds must be "sealed in." This may be accomplished by means of sound-absorbing walls surrounding the transformer, but this is a remedy which seldom can be used.

Source number 2 may be of importance in certain installations where large areas may be set in vibration by transmission of vibrations through materials like steel or concrete which transmit vibrations much more readily than air. Such vibrations may be reduced by elastic support between the transformer base and

Suppression of Magnetic Vibration and Noise of Two-Pole Turbine Generators

A. L. PENNIMAN, JR.
MEMBER AIEE

H. D. TAYLOR
MEMBER AIEE

THE constant striving for improvement in over-all economy in the generation of electric power by steam has resulted in the last three or four years in a rather rapid increase in the capacity of steam turbine generators built to operate at 3,600 rpm. One of the factors contributing to this growth was the progress made in the use of high-pressure and high-temperature steam which led to the application of a number of such turbines for superposition on existing comparatively low-pressure steam plants, as well as for straight through condensing operation. The operating experience with such recently developed 3,600-rpm generators ranging in capacity up to 66,667 kva has been unusually good. The troubles which have been experienced, either mechanical or electrical, have not been of a serious nature.

While 3,600-rpm generators have been built for many years, the double-frequency vibration and noise produced by them was not until recent years of much moment or concern. The comparatively recent machines with which we are here concerned are large as compared to the earlier ones and have in many cases produced an objectionable amount of 120-cycle noise and vibration, the noise being often an intense humming of all-pervading character, seeming to go all through the plant. The intensity of the noise, at some points, is materially affected by reflection from various smooth surfaces, being particularly loud where the reflected sound wave reinforces the original.

In addition, the actual amplitude of the mechanical vibration has been sometimes sufficient to result in severe vibration of many parts of the station structure or equipment such as beams, brackets, floor plates, housings or parts of them, even exciter brush arm brackets, latch mechanisms, or perhaps delicate relay parts. This is particularly so if the natural period of vibration of some beam or part is in resonance or near resonance with the vibration source.

Early investigations of the 120-cycle vibration and noise showed that they resulted when field excitation was applied to the generator and that in fact they were two aspects of the same disturbance. This definitely indicated that the cause was magnetic. The disturbance, as has been pointed out in a previous paper,[1] is due to the magnetic forces of a two-pole field rotor bringing about a distortion of the stator into an elliptical shape, the distortion revolving in synchronism with the rotor. Since each pole of the rotor pulls the stator radially inward, any point on the stator core vibrates at a frequency double that of rotation, or at a frequency of 120 cycles for a 3,600-rpm machine.

As is well known, the magnetic force of attraction between the stator and rotor at any given point varies as the square of the flux density at that point. Figure 1 has been plotted in terms of magnetic force or pull as determined from the flux distribution typical of a two-pole machine.

While the magnetic vibration has not been severe enough to have any apparent effect on the life of the stator winding or other parts, nevertheless, the noise has in many instances been so intense as to be very annoying to live with, which indicated that there was a need for some means of suppression or mitigation of this noise and vibration and led to the undertaking of a careful analysis of the problem. The presentation of the various phases of this analysis, together with a description of the development of an apparently complete cure for the double-frequency magnetic vibration nuisance by means of a simple form of resilient core mounting, is the subject of this paper.

Observations on Magnetic Vibration

Since the double-frequency vibration and noise are caused by distortion of the generator stator structure, the amount of this distortion is of primary importance. The frequency being high, special equipment is required for accurate measurement. Readings of vibration amplitude taken with an optical amplitude indicator on a representative large two-pole machine of early design are shown in figure 2. These were taken radially on the surface of the stator, and the plot shows the variation in amplitude along the length of the machine. The same curve applies to either side or the top of the generator, or at any angle in between, for *radial* amplitudes. With excitation removed, this vibration disappears, although there is usually a residual vibration at running speed frequency, transmitted from the rotor, which is small if the machine is well balanced. The residual vibration in this case is shown by the dotted curve.

The variation of this double-frequency

Paper 41-39, recommended by the AIEE committee on electrical machinery, and presented at the AIEE winter convention, Philadelphia, Pa., January 27–31, 1941. Manuscript submitted November 15, 1940; made available for preprinting December 10, 1940.

---

the foundation. This elastic support should be correctly designed, otherwise its effect may be very detrimental. The elastic support should have a natural frequency considerably below the lowest impressed vibrational frequency produced by the transformer. Spring supports are, in general, not practicable. There are on the market special high-grade rubber compounds which do not lose their resilience appreciably with time.

The problem of transformer sound and methods for its reduction is far from being solved. With the exception of reduction in magnetostriction, no means have been found by which the sound level may be economically reduced. Continued research is being done on this problem. The company with which the writer is associated has a large soundproof room which is used to facilitate such investigations. This room has inside dimensions of 24 feet by 25 feet and 22 feet height. It is of a double-room construction. The outer room is of eight-inch brick walls with a seven-inch thick concrete roof. The inner room is completely insulated from the outer room. Its walls and ceiling are constructed of sound-absorbing material particularly effective for frequencies in the range from 100 to 1,000 cycles. A seven-inch air space separates the two rooms. The average attenuation is of the order of 55 decibels, which is sufficient for the work for which the room was designed.

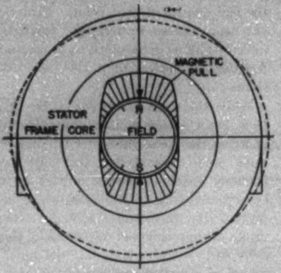

Figure 1. Magnetic pull of a typical two-pole a-c generator

amplitude with speed is shown in figure 3. It may be noted that, as speed is reduced below 3,600 rpm, with constant excitation, the amplitude drops off somewhat, but levels off to a definite value for zero speed. The shape of this curve is similar to part of a resonance curve, and suggests that if the speed could be carried considerably beyond 3,600 rpm, the amplitude would increase greatly, perhaps reaching a peak value at some higher speed.

Analytical Approach to Problem

Consideration of data such as are shown in these figures suggested an analytical approach to the problem to account for the observed vibration, along the following lines:

(1). Evaluation of the magnetic forces acting radially in the air gap between rotor and stator;

(2). Calculation of the deformation of the stator structure by these forces, considered as acting statically, that is, with the rotor at rest;

(3). Estimation of a resonance "build-up" factor (ratio of running amplitude to static deformation) based upon the relationship of the frequency of the magnetic forces at running speed to the natural frequency of the stator vibrating as a cylindrical ring with a four-node pattern.

Tests on Stiffness of Stator Elements

The magnetic forces were found to be rather large, equivalent roughly to two concentrated opposite radial loads on the stator of the order of 50,000 to 100,000 pounds each in large machines. The static deformation of the stator frame by such forces, assuming at first that the core laminations had no stiffness of their own, was calculated by well-known ring formulas[2,3] to be far greater than the observed vibration. It seemed therefore that the laminations must contribute a large share of the total stiffness of the stator. As a check on this point, deflection tests were made on a full-sized stator frame of greater than average stiffness before and after the laminations were assembled, with results as shown in figure 4. The frame was set on the factory floor and loaded with heavy rotor forgings laid on top of it on wooden chocks, and the deflection measured by means of dial indicators set to register the change in the vertical diameter. Upon removal of the loads, the indicators all returned to zero. It will be noted that with the heaviest load, the bare frame deflected 10.5 mils, as compared with 1.3 mils after assembly of the core.

In anticipation of these results, and to settle the question as to whether this great stiffness was a property of the tightly pressed core itself or depended upon assembly of the core in the frame, a ring had been made of some of these same laminations pressed together with rectangular steel bars as shown in figure 5. This ring was also subjected to deflection tests, by loading it across a diameter with a hydraulic jack, and measuring the deformation with dial indicators in much the same way as on the frame. It was found that this ring of punchings was quite elastic; that it would take loads up to several times the normal magnetic load, and return to its original shape; and that it was exceedingly stiff, sufficiently so to account fully for the difference in stiffness between the bare frame and the stacked frame. Also, while the ring stiffness varied somewhat with the tightness of clamping, this effect was comparatively slight so long as the laminations were reasonably tight. In short, the core was found to be a cylinder of great strength and stiffness independent of the generator frame.

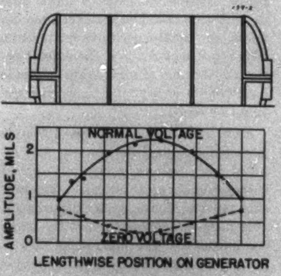

Figure 2. Distribution of vibration on stator of a two-pole generator

Tests to Determine Natural Frequency of Core

Other rings of punchings were tested with similar results. Further tests were made on them to determine the natural frequency as a cylindrical ring vibrating radially with a four-node pattern. The two types of tests, for static stiffness and for natural frequency, were correlated, and it was found possible to calculate the natural frequency of a core structure with reasonable accuracy. In all cases, it was found to be high, of the order of 160 to 200 cycles in the largest machines, and higher in smaller machines.

Use of Resonance Curve in Calculating Magnetic Vibration

This information made it possible to carry through with the three steps suggested for the calculation of the amplitude of magnetic vibration of two-pole generators in general. The stiffness of the frame usually being small in comparison with that of the core, little error results from leaving the frame entirely out of the calculations. The first two steps, to determine the magnetic forces and the resulting static deflections of the cylindrical ring of punchings, are carried out by well-known methods that do not need to be repeated here. The third step makes use of a resonance curve such as that shown in figure 6. Here amplitude is plotted against the frequency of the deflecting force. For zero frequency, i.e., a steadily applied force, the amplitude is shown as 1.0, which represents the static deflection. With increasing frequency, the amplitude increases and reaches a peak value at resonance, when the frequency of the deflecting force equals the natural frequency of the setup. The frequency scale is also on a per-unit basis, with 1.0 representing resonance. For higher frequencies beyond resonance, the amplitude decreases rapidly. This relationship between amplitude and frequency is rigorous[4,5] for any simple system in which the disturbing force remains constant in magnitude

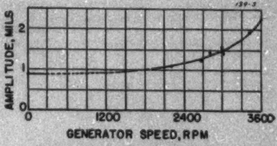

Figure 3. Variation of magnetic vibration with speed

as the frequency varies. It has been assumed to apply to a cylindrical ring. Damping has been neglected; if taken into account it would reduce materially the amplitudes near resonance, as shown by a sample dotted curve. However, the four-node natural frequencies of the generator cores were found to be so far above the impressed frequency of 120 cycles that damping can be neglected. The use of the curve is fairly obvious. It merely shows a "build-up" factor, representing the increase of the running amplitude above the static deflection. For example, if the natural frequency of the stator core is determined as 200 cycles the ratio of impressed frequency to natural frequency is 120/200 or 0.6; and the "build-up" factor is 1.56.

Improvement Obtained by Increased Radial Depth of Core

Calculations were made along these lines for all large 3,600 rpm generators made by the General Electric Company. Agreement between the calculations and the maximum of test observations similar to those plotted in figure 2 was very satisfactory. It was obvious from the results that considerable reduction in the vibration could be obtained by the use of punchings of increased radial depth. The greater stiffness of such "deep core" machines helps in two ways: (1) it reduces the "static" deformation; and (2) it increases the natural frequency so that the "build-up" factor is also reduced. Deep-core construction has been used in quite a number of generators in the past two years, with a gratifying reduction in the double-frequency disturbance. The ratio of improvement in the largest machines has been of the order of two to one.

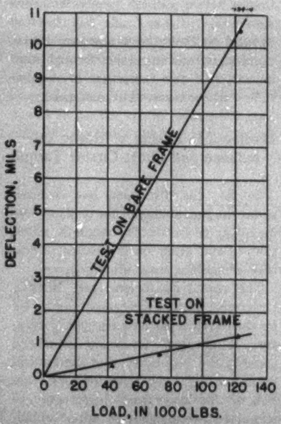

Figure 4. Results of deflection tests on stator frame

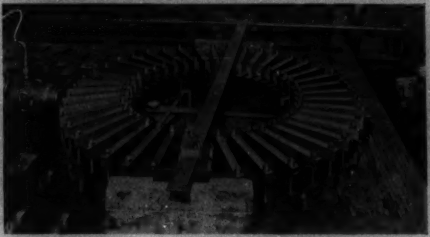
Consideration of Resilient Mounting of Core to Isolate Vibration

Although the improvement obtained by the simple expedient of deepening the core was considered to be sufficient to remove most of the nuisance effect of the noise and vibration in all cases where station acoustics are reasonably good and mechanical resonance is avoided in adjacent structures, nevertheless it seemed desirable to see what could be done to eliminate the magnetic disturbance almost entirely. A suggestion to this end had been made by L. P. Grobel, shortly after the first large 3,600-rpm generators came to test. His proposal was to isolate the vibration by mounting the core on spring members within the stator frame. This seemed like a rather radical departure, but the tests described in preceding paragraphs demonstrated that the tightly pressed laminated cores had great strength and stiffness of their own, and indicated that the isolation idea was an inviting possibility. A number of complications, however, had to be faced. First, should the spring members provide radial flexibility only, and be rigid tangentially; or should they be flexible both ways? Second, if the frame is not attached rigidly to the core, its own four-node natural frequency will determine its response to the stimulation coming through the spring members, and must be taken into account. Third, the core should apparently be mounted in such a way that it will not have natural frequencies for bodily motions which would cause it to respond unduly to the running speed frequency disturbances caused by unbalance of the rotor. Fourth, the core mounting must be designed to withstand the severe torsional effect of short circuits. A complete treatment of these matters is entirely beyond the scope of this paper. They will be briefly discussed, however, in the next few paragraphs.

Figure 5. Setup for deflection tests on ring of core laminations



Tangential Displacements of Cylindrical Rings

A tangentially rigid but radially flexible type of mounting was suggested independently by several engineers within the General Electric Company, and was given serious consideration. Its effectiveness would apparently depend upon the amount of tangential vibration accompanying the radial vibration at the point of attachment, at the outside diameter of the core, or farther out if a double frame should be used. It is not at once obvious that there should be any tangential motion at all, although it was pointed out long ago by Lord Rayleigh[8] that in the case of a *thin* circular ring, elliptical distortion or four-node vibration resulted in a tangential displacement of the nodal points equal to just 50 per cent of the maximum radial displacement. This is illustrated in figure 7, from which the reason for the tangential displacement may be seen. The distance around a quadrant of the deflected ring, from one 45-degree point to the next, is obviously greater across the major axis than across the minor axis, so that, unless the ring is forcibly stretched in two quadrants and shortened in the other two, the "nodal" points at 45 degrees must move tangentially.

Two-pole generator cores, however, are not thin rings, but relatively deep ones. An investigation was made to determine how the tangential displacement might vary with the ring depth. The curves in figure 8 are drawn to illustrate some of the results of an analysis made by Doctor H. Poritsky and H. D. Snively. These show that deep rings have a tangential displacement of more

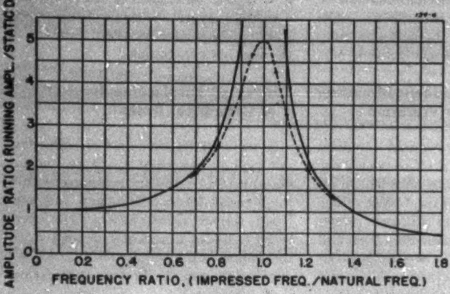


Figure 6. Basic resonance curve

than 50 per cent of the radial displacement, at the inside diameter; but less than 50 per cent at the outside. The exact values depend upon the depth ratio (outside diameter)/(inside diameter). Amplitude observations during the tests for the natural frequency of rings of punchings, described in a previous paragraph, gave an excellent check on these curves, as shown by the *X* points (figure 8). It seems that for two-pole generator cores of normal proportions, with a ratio of outside to inside diameter (over the slots) of 1.5 to 1.6, the tangential vibration on the outside diameter is likely to be about 20 per cent or more of the radial vibration. Now, the frame may also be considered as a deep ring, with a ratio of outside to inside diameter of the same order of magnitude as the core. Consequently, the tangential vibration at the *inside* diameter of the frame is likely to be about 80 per cent of its radial vibration. Thus, if the point of attachment for a tangentially rigid core mounting is at the outside diameter of the core, something like 20 per cent of the radial vibration of the core would be tied in rigidly with 80 per cent of the radial vibration of the frame. The result would be a reduction of about four to one in the radial vibration at the surface of the frame. Such an improvement would be quite worth while, but it was felt that a higher ratio of reduction would be desirable.

Importance of Natural Frequency of Stator Frame

Consideration of a resilient mounting having both radial and tangential flexibility indicated that an improvement ratio of 10 or 20 to 1, or even higher, could be obtained by suitable design of the spring members and the frame. In brief, the spring members must be relatively flexible, and the frame relatively stiff. The static performance of such a combination is readily calculated. The vibrational loading of the frame is computed as the product of the amplitude of the core and the gradient of the spring members. This neglects the yielding of the frame, which is intended to be negligibly small anyway. Both tangential and radial loading must be taken into account. However, the running performance depends upon the natural frequency of the frame, in the same manner as the running amplitude of the core depends upon its natural frequency. Strictly, the core, spring members, and frame form a compound elastic system with two natural frequencies, both of which are different from the natural frequencies of the core and frame considered separately. The behavior of such a system has been carefully worked out by methods described in chapter V of reference 4. With the aid of some simplifying assumptions, however, calculation of the running performance to a close degree of approximation can be made, using the ordinary basic resonance curve of figure 6. The effect of the frame and spring members on the stiffness, natural frequency, and running amplitude of the core is neglected; but a correction to the natural frequency of the frame due to the spring members may be required, especially if the frame frequency is low, below 120 cycles. The static deformation of the frame, which would be produced by the combined radial and tangential loading due to the *running* amplitude of the core acting on the spring members is calculated, and multiplied by the "build-up" factor based upon the natural frequency of the frame.

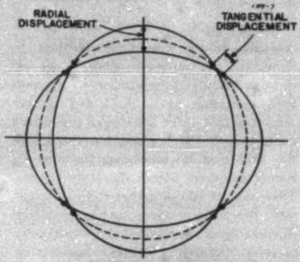

Figure 7. Sketch illustrating tangential displacements for a thin ring

For this purpose, it is of course necessary to know the four-node natural frequency of the frame. To date, it has been necessary to use test information on this point. Test equipment available for vibrating turbine wheels and buckets has been used with the addition of some small but powerful a-c magnets, which are set to pull diametrically across the bore of the frame under test. Even the largest and heaviest frames are set into vibration in this way, and by varying the frequency of the a-c supply to the magnets, the resonant frequency of the frame is readily determined. In general, it is felt that a high natural frequency (above 120 cycles per second) is desirable for frames to be used with resiliently-mounted cores, for the reason that it avoids a "critical speed" or resonance peak of frame vibration which would otherwise occur below running speed, if the generator is brought up or down with excitation. It is undoubtedly practical, however, to use resilient mountings with frames having natural frequencies below 120 cycles, if the frame can be well damped to limit the momentary vibration encountered in passing through resonance, or if the excitation is reduced sufficiently or removed at that speed.

Mechanical Effects of Rotor Unbalance and Short-Circuit Torque

So far, the discussion has centered about the functioning of the resilient core mounting to isolate the magnetic vibration. Now, attention is directed to possible difficulties from other sources.

The core, end flanges, and winding structure, taken together, comprise by far the heaviest part of a two-pole generator. If "floated" on spring members, there is the possibility that mechanical resonance might take place for bodily motion of this heavy mass in response to stimulation coming from rotor unbalance. Considered as a simple mechanical system with the frame support on the foundation assumed to be rigid, the obvious solution is to make the natural frequencies of the core on the spring members low for both translation, i.e., "straight bouncing," and for rotation about an axis at right angles to the shaft, which can be called "rocking." Actually, the foundation is never rigid; for large machines it is far from being so, especially in the horizontal plane. The result is a complicated elastic system, comprising the rotor, the frame, and the spring-mounted core (not to mention the turbine), all mounted on a foundation of considerable mass and with flexibility both for horizontal and vertical motion. Such systems have been investigated by E. H. Hull, using a novel experimental technique described in a recent paper.[7] He finds a whole series of resonance speeds, depending upon the critical speeds of the rotor (as calculated for rigid bearing supports) and the natural frequencies of the spring-mounted core, as well as the mass and flexibility of the foundation. Fortunately, it seems to be possible to control these resonance speeds, for ordinary values of shaft criticals and foundation characteristics, by making the natural frequencies of the spring-mounted core rather low, say, of the order of 1,200–1,500 vibrations per minute. Also, none of them involve much vibration if the machine is properly balanced.

Special consideration must also be given to the severe transient short-circuit torques characteristic of turbine generators, in order that the spring members shall not be overstressed. Instantaneous peak values of the applied torque, although they may be many times normal rated torque, are ordinarily not high enough to cause concern in this respect. Their magnitude is usually of such an order as would about take the gravity load off one foot of the generator and double it on the other. Since the considerable inertia of the core is interposed between the short-circuit torque, applied at the air gap, and the spring members outside the core, the stresses in the spring members are not a direct function of the applied torque alone but depend upon the torsional displacement of the core relative to the frame. This displacement can be calculated by methods[8,9] previously developed for analysis of short-circuit torques at the couplings of turbine-generator sets.

These methods are rather well known, but a few remarks about them might be in order here. The simplest approach considers the torques as suddenly applied, but neglects the decrements, and assumes a rigid foundation such that the torsional system has only one natural frequency. On this basis, the maximum displacement may be computed as the sum of a series of components of displacement which occur at the applied torque frequencies (principally 60 and 120 cycles) and also at the torsional natural frequency of the system. Each of these components is a function of the frequency ratio (impressed frequency/natural frequency), in a manner very similar to the basic resonance curve of figure 6. However, it appears advantageous in this case to keep the torsional natural frequency well below the lowest frequency of the impressed torque. When foundation flexibility is taken into account, the system becomes a compound one with two natural frequencies. The analysis becomes considerably more elaborate but has been worked out fully on the basis of neglecting the mechanical damping and the torque decrements. These assumptions, of course, are on the safe side, but before this study of short-circuit torques can be considered complete, these factors must be taken into account. In general, however, it is found that foundation flexibility reduces the maximum displacement of the core relative to the frame below that which would occur on a rigid foundation.

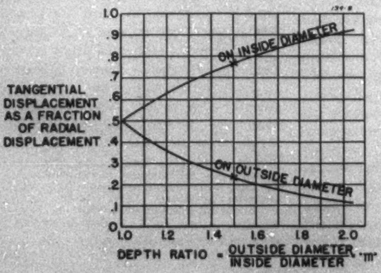

Figure 8. Tangential displacements in deep rings

Description of Resilient Core Mounting as Built

A resilient core mounting and a nonresonant stator frame were designed along these lines for a 31,250-kva air-cooled generator. A photograph of the frame is included as figure 9, and figure 10 gives a close-up view of the assembled spring members. These are twin sets of spring bars of rectangular section, attached by bolting and welding to the bore of the frame and arranged in three groups lengthwise. The long dovetail key bars on which the core is stacked, are attached by body-bound studs to the centers of the spring bars, which provide a sturdy tie between the core and the frame, rigid lengthwise but with some flexibility both in the radial and tangential directions. The spring bars are really beams with fixed ends, and with heavy bosses at their centers where they are bolted to the dovetail key bars and also at their ends where they are attached to the frame, so that there are no moving joints to wear out. Fatigue seems to be completely out of range for these bars, as the alternating component of stress is of the order of two per cent of the elastic limit of the material, superposed upon steady gravity stresses of about 20 to 25 per cent. And fatigue needs to be out of range, as at 120 cycles per second these bars must undergo more than 10,000,000 cycles of duty per day. The frame was also specially designed, to have a high four-node natural frequency, well above 120 cycles. The test value on the bare frame, without end shields, was 201 cycles. On this basis, the expected performance of the resilient core mounting was a reduction of the magnetic vibration from core to frame of about 30 to 1. When this machine came to test at the factory, it met our expectations fully. In fact, no 120-cycle vibration could be detected at the middle of the frame, by touch or by

Figure 9. Frame of 31,250-kva generator with resilient core mounting

means of optical vibration indicators, Frahm vibrating reed tachometers, or a vibration-velocity pickup device connected to a cathode-ray oscillograph. The core was reached by means of rods inserted through small holes drilled in the frame, and showed about 1.3 mils of magnetic vibration. But it was impossible for a man standing alongside the generator to tell, by touch or by hearing, when excitation was applied or removed.

Operating Results

This 31,250-kva air-cooled generator, as built with resilient core mounting and nonresonant stator frame, was installed at the Westport plant of the Consolidated Gas Electric Light and Power Company of Baltimore, Maryland, and went into service on August 10, 1940. Figure 11 shows this generator and driving turbine as installed at Baltimore.

The turbine driving this generator was built for operation at a throttle pressure of 1,250-pounds gauge 900 degrees Fahrenheit, being supplied with steam from two high-pressure boilers. The turbine exhausts into the 200-pound steam mains of the earlier Westport plant but with piping arranged for specific superposing if desired on two 25,000-kva 200-pound regenerative condensing units, which were the last 200-pound units installed at Westport.

The operation of this superposed 3,600-rpm unit has well demonstrated the value of the new core mounting for suppression of 120-cycle core noise and vibration, the operating results being quite in agreement with the factory tests. In actual service, a man standing alongside of the machine could not detect by touch or hearing the application or removal of field excitation.

Other machines incorporating the improved type of core mounting are now being built, and it is expected that this feature will be applied to many 3,600-rpm generators of the future.

High-Potential Testing Equipment for Quantity Production

C. M. SUMMERS
MEMBER AIEE

Introduction

MANUFACTURERS of electrical apparatus and appliances are aware of the value of high-potential insulation tests and have endeavored constantly to improve testing facilities and methods. Practical circumstances very early gave rise to the practice of applying a short-time test voltage substantially above the normal excitation of the apparatus or appliance. Because of the availability and simplicity of amplitude control, alternating voltage of ordinary power frequency has been used and the test voltage levels have been developed through operational experience. Occasionally circumstances have made the use of power frequency impractical; hence higher frequencies and direct voltage have been resorted to. Also, surge voltage tests have been used increasingly in an effort to simulate transient voltages which occur in field circuits.

For large apparatus and for high-voltage equipment the dielectric testing sets have been standardized and the testing procedure has been generally established. In this field a generous amount of time can be allowed for conducting tests, because the quantity of apparatus manufactured is comparatively low.

Because of the large quantity of small apparatus and low-voltage equipment now manufactured, high-potential testing must be co-ordinated with production circumstances where rates of 20 or 30 complete dielectric tests per minute are commonly encountered. Accordingly, the recognized practice of gradually raising and lowering the test voltage is entirely impractical from the standpoint of time consumed. Consequently many of the factors which have been so carefully considered in the high-voltage field have been neglected in low-voltage testing.

The purpose of this paper is to point out that the simplicity of low-voltage testing does not obviate surge voltages and that the same general fundamental factors established for high-voltage testing also apply to low-voltage testing. In this paper an attempt has been made to evaluate the surge voltages in terms of their effect on the breakdown of insulation. First, a cathode-ray oscillograph study was made to determine the magnitude of the surges. Then a number of comparison tests were made on a selected insulation to determine the comparative breakdown strength with and without influence of the surges.

As a result of these investigations it was found that the magnitude of the surge voltage varied considerably depending on the method used for limiting the short-circuit current and on the characteristics of the dielectric. In some instances, surges of 100 per cent above the normal test voltage were measured. In a controlled test, the surges reduced the apparent breakdown voltage of a specific insulation by roughly 25 per cent. It has been found that a properly co-ordinated high-potential transformer and a resistance potentiometer control forms a suitable system for testing low-voltage apparatus. The system is relatively free from surge voltages and it does not interfere with high-speed testing. This method also has led indirectly to the development of a cathode-ray fault detector which has been very useful in analyzing the physical characteristics of the dielectric and the type of failures that occur.

Present Practice

The testing equipment for this low-voltage apparatus can be obtained and installed with comparative ease in any production line. The test voltage can be conveniently controlled and easily applied. Usually, some means of limiting the short-circuit current is employed in order to minimize the material damage to the apparatus or appliance in case the dielectric fails. A pair of insulated electrodes, called stickers, permanently connected to the high-voltage terminals of the high-potential transformer, is commonly used to apply the test voltage between the windings and the frame or ground of the apparatus under test. In some cases, however, two or more units may be connected in parallel to the high-potential testing transformer which is then energized for a brief period of time. In either case, surge voltages are liable to occur in the high-voltage circuit which casts some doubt on the effective value of the test voltage.

Switching Surges

It is common knowledge that the interruption of the excitation circuit of a transformer will produce a transient voltage across its terminals. The amplitude of the impulse is proportional to the rate of change of flux in the magnetic circuit, and it is dependent on the position on the

Transformer controlled by potentiometer normal crest voltage 3,530 volts

flux-time curve at which the circuit is opened. Whenever high-potential testing methods employ low-voltage switching, it is obvious that the dielectric circuit will be subjected to an indefinite abnormal voltage. Furthermore, the maximum amplitude of the surge may occur when the transformer is de-energized at the conclusion of the test. The dielectric may fail at this final instant and if it does, it may not be detected unless a subsequent test is made.

High-voltage switching is employed every time the stickers are applied and removed from the apparatus. An arc occurs when the stickers are applied and another when they are removed. The testing circuit, consisting of resistance, inductance, and capacitance, may have excessive transient voltages induced in or applied to all parts of the circuit during this arcing period.

A cathode-ray oscillograph connected as shown in figure 1 will indicate the actual voltage to which the dielectric is subjected. When the contact at *A* is solidly closed the normal transformer voltage is applied to the dielectric. However, when an arc is established at *A* a series of transients or impulses are impressed on the test piece at the beginning of each one-half cycle. The oscillogram in figure 2 shows this condition for a common type of testing circuit. This shows a crest voltage of over 5,000 volts whereas the steady-state test voltage had a crest value of 3,500 volts. This is somewhat equivalent to superposing an impulse on the power frequency. It has been observed in the past that under these conditions a flashover of an insulation may not be followed by a power arc, particularly when the total voltage amplitude is near the flashover value for that insulation. Under the somewhat similar conditions as illustrated by figure 2, the insulation may be partially damaged, by a pinhole puncture, for example, which has not been followed up by a power arc. This may be a sufficient cause for a future failure at a lower test voltage. This experience indicates that it is desirable to maintain a sinusoidal voltage on the test piece throughout the entire test period.

Field Data

In order to obtain some field data on the effect of arcing surges some special tests on fractional-horsepower motor armatures were conducted with a pair of stickers connected in parallel with the regular production line. The armatures were tested at 1,500 volts, but would normally withstand 2,500 volts. The test pair of stickers was connected to an armature and an arc maintained between one sticker and the winding for a period of time. Five consecutive armatures were broken down on the production line during this test, although a voltmeter still indicated an rms test voltage of 1,500 volts.

Table I. Effect of Surges on Dielectric Strength of Paper

Sample Number	Breakdown Voltage—No Arcing (Voltmeter Readings)	Breakdown Voltage Arcing to Simulate Removal of Stickers (Voltmeter Readings)
1	1,330	1,170
2	1,670	1,330
3	1,700	1,280
4	1,860	1,375
5	1,430	1,265
6	1,460	1,170
7	1,400	1,230
8	1,670	1,330
9	1,530	1,350
10	1,400	1,200
11	1,370	1,140
12	1,310	1,150
13	1,370	1,170
14	1,400	1,220
15	1,670	1,330
16	1,700	1,310

In another instance, a plate-glass condenser was used as a dielectric load and during the arcing period a sufficiently high-surge voltage was established to flash over the one-fourth-inch plate glass of the condenser, although the test voltage as indicated on an instrument remained at 2,500 volts. The condenser had a sinusoidal flashover value of 6,000 volts.

A test circuit shown in figure 3 was established to measure the effective breakdown value of the surges initiated by an arc in the high-voltage circuit. The sphere gap *G* represents the stickers and it was used merely to control the arc and not to measure voltage. Past experience has indicated that the capacitance of the dielectric of low-voltage apparatus and appliances varies from 0.0005 to 0.002 microfarad. A 0.001-microfarad capacitor, chosen as a representative load, was connected in series with the gap so that the voltage across it is comparable to that across the dielectric of the apparatus in actual practice. A transformer having about three per cent reactance was used for the source of high potential. Several selected samples of an insulation, consisting of four layers of 0.0005 condenser paper, were used as test specimens and connected directly across the capacitor. Each specimen was large enough to obtain two breakdown tests, one when a sinusoidal voltage was applied and the other when surges were produced by the arc. The first test was obtained by closing the sphere gap *G* and raising the primary voltage very slowly by means of a variable-voltage autotransformer until breakdown occurred. The second test was obtained by setting the primary voltage at some low value and opening the gap *G* until the arc was extinguished. (This action simulates the removal of stickers from the apparatus.) The sup-

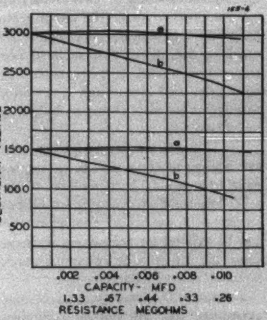

Figure 6. Voltage-regulation curve of 0.25-kva 3,000-volt potentiometer-controlled transformer

a—Capacitance load
b—Resistance load

ply voltage was raised in small increments and the procedure repeated until the specimen broke down and in each case the rms voltmeter readings were recorded. The results, shown in table I, indicate that the breakdown voltage is 20 per cent lower when the surges are present or in other words the dielectric is subjected to a higher level than the voltmeter indicates.

Surge voltages varying from 25 per cent to 100 per cent above the test voltage are commonly found in testing installations employing stickers, and utilizing reactance to limit the short-circuit current. Even when reactance is not deliberately introduced to limit the current, and when a testing transformer of normal design with less than five per cent reactance is used, the surges are still present. They may not be severe for many types of apparatus where the factor of safety is large. Furthermore, the degree of damage the surge can create in the insulation has not been conclusively established. The serious factor involved, however, is the uncertainty of the actual voltage to which the dielectric is subjected.

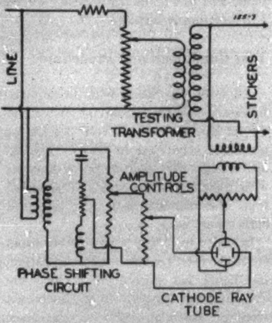

Figure 7. Circuit diagram for potentiometer-controlled testing transformer and cathode-ray fault detector

Methods of Reducing Surge Voltages

Resistance inserted in the high-voltage circuit in series with the test load will greatly reduce the surges appearing across the dielectric. In one case it was found that 50,000 ohms in the secondary of a 0.25-kva low-reactance transformer reduced the surges to a negligible amount. An equivalent resistance on the low-voltage side of the transformer similarly reduced the surges. A circuit shown in figure 4 has been found to be relatively free from all types of surges caused by low- or high-voltage switching, because the parallel resistance tends to absorb the energy of the low-voltage switching.

The effectiveness of the potentiometer control was demonstrated in the following manner. A transformer with a rating of 0.25 kva with three per cent reactance and a secondary voltage of 2,500 volts with 110 volts on the primary was supplied from a variable-voltage autotransformer. Surge voltages initiated by low-voltage and high-voltage switching were measured across a 0.003-microfarad capacitor load. The value of the surge most often obtained is given in table II as a percentage of the open-circuit secondary peak voltage.

Table II. Surge Voltages in a Circuit Controlled by a Variable-Voltage Autotransformer

Normal Secondary Voltage	Surges in Per Cent of Normal Secondary Peak Voltage: Primary Switching	Secondary Switching
2,500	200	250
1,500	200	200
900	200	200

The variable-voltage autotransformer then was replaced by a potentiometer, or a resistance control as in figure 4 and the switching repeated. The results are shown in table III. A typical oscillogram of the high-voltage switching surge is shown in figure 5, and compares with figure 2 for the previous case. Satisfactory operation is thus assured with the potentiometer control if the series portion is limited to some predetermined minimum value of resistance and also if the parallel portion is limited to some maximum value.

Any type of testing circuit will supply a limited load when some means of current limitation is employed. Figure 6 shows the voltage-load curves for a potentiometer-controlled circuit. The capacitance of the dielectric circuit does not have a great effect on the regulation, curve *a*, especially in the range encountered in low-voltage apparatus. The resistance of the dielectric, however, does cause an appreciable regulation, curve *b*. Therefore, if it is desired to maintain a regulation of less than three per cent the resistance of the dielectric should not be lower than three megohms.

The high-voltage wave form can be maintained reasonably sinusoidal. If the series resistor alone is used, the normal exciting current required by the transformer causes an appreciable voltage distortion. If, however, the current through the resistor *ab* in figure 4 is approximately three times the value of exciting current, the wave form is acceptable, with a harmonic content of less than five per cent. The amount of distortion, of course, depends materially on the degree of saturation in the transformer core, but if this is maintained at a reasonable value, a good high-voltage wave form can be maintained.

Table III. Surge Voltages in a Circuit Controlled by a Potentiometer

Normal Secondary Voltage	Series Resistance (Ohms)	Parallel Resistance (Ohms)	Surges in Per Cent of Normal Secondary Voltage: Primary Switching	Secondary Switching
2,500	73	250	104	100
1,500	420	250	103	100

circuits because the voltage on both sides of the transformer drops in accordance with the severity of the failure in the dielectric. If the organic dielectric materials are moist, due to high humidity, the conduction current will be high, and the transformer regulation will cause the voltage to drop. Usually a high-leakage current will not destroy the insulation, but it will cause a definite indication of some abnormal condition.

A cathode-ray oscilloscope has proved to be a very useful tool in connection with the testing circuit shown in figure 4 for analyzing the type of faults that may occur in dielectrics.

Cathode-Ray Oscilloscope Fault Detector

Figure 7 shows the circuit diagram of the dielectric testing transformer, potentiometer, and cathode-ray circuit. The adjustable phase-shifting circuit permits the voltage on the horizontal plates to be shifted 90 degrees from the test voltage. The amplitude of voltage on both the horizontal and vertical plates can be adjusted so that the image on the cathode-ray tube screen can be made to appear as a circle as shown in figure 8*a* for the normal test voltage. When voltage is applied to a test sample through the stickers, the image will remain unchanged if the dielectric is perfect. If the insulation contains excessive moisture there will be a high value of conduction current, hence the voltage on the vertical plates will drop and the image on the cathode-ray tube will change to an ellipse as in figure 8*b*.

A high-capacitance current flowing through the dielectric, will cause a phase shift in the test voltage, hence the image will appear as an ellipse with an inclined axis as in figure 9*b*. Corona streamers in the dielectric will cause the image to appear as shown in figure 10, while an arc jumping across or through the insulation will change the image to figure 11. A complete short circuit produces a horizontal line as in figure 12*b*.

Conclusion

The data presented in this paper is by no means conclusive. It does not infer that all types of high-potential testing equipment are dangerous to insulating material, nor does it prove that all testing methods are improper. It has brought out the possibility that indefinite surge voltages may exist and that these surges may cause some damage to the insulation. These hazards arise, however, only when some fundamental principle has been violated, such as low- and high-voltage switching. The use of resistance for reducing surge voltages is not new. It has been shown, however, that either low-voltage or high-voltage switching may be employed without creating dangerous surges when the resistance is properly used. Thus, high-speed testing may be conducted to meet any production requirement and at the same time a definite predetermined test voltage can be maintained. There may be other methods of accomplishing the same result, but the resistance control seems to be the most expedient.

The cathode-ray fault detector is a very useful tool in connection with the resistance-controlled transformer. It enables one to determine by a glance, the wave form and magnitude of the test voltage, some of the physical properties of the insulation, and whether or not streamers or corona are present. The voltage which a material will withstand can be readily determined, and unseen flashovers can be detected by careful observation of the screen. If the power arc follows the flashover either momentarily or continuously, it too can be observed. The cathode-ray fault detector may not be practical to use in high-quantity production because of the longer time consumed in making the observations, but it is very useful in laboratory or other work where time is not so important.

Arc-Backs in Ignitrons in Series

J. SLEPIAN
FELLOW AIEE

W. E. PAKALA
ASSOCIATE AIEE

Synopsis: Theory based on the random occurrence of arc-backs indicates that the arc-back rate of ignitrons in series should be very low compared with the arc-back rate of the individual ignitron operating alone on its share of the voltage. To check these ideas, experiments were carried out with high-current ignitrons (350 amperes average per anode) operating in series with voltages balanced and unbalanced, and individually. The results of these tests are given and discussed.

Introduction

THE ignitron is a single-anode mercury-vapor rectifier with a mercury-pool cathode and a stationary electrode, called the ignitor, partially immersed into the cathode pool. A current of a few amperes at about 100 volts passed through the ignitor initiates the arc once each cycle and at any time desired in the cycle. The use of ignitrons with the usual rectifier-transformer connections gives a power-converting system with all the advantages of grid-controlled rectifiers at higher efficiencies, since no grids are required near the anode for the control of load.

In the last few years the use of ignitrons commercially has been greatly accelerated and single assemblies up to 3,000-kw capacity at 600 volts are in service.

Research work continues on the still baffling problem of arc-back. Accepting the arc-back rates as obtained on commercial tubes, however, it seemed desirable to check whether the lower arc-back rate for ignitrons in series, as predicted by the theory of random arc-back could be really obtained.

Two ignitrons were tested in series and individually, at water temperatures abnormally high, and without baffles and shields, so that arc-back rates were high enough for conclusions to be drawn in not too excessive a time. It was found that the two ignitrons in series under these conditions would operate with an average of 13.75 hours per arc-back, whereas an individual ignitron at *half the voltage* would operate with an average of only 0.0442 hours between arc-backs. The calculated value was 16.4 hours per arc-back for the two ignitrons in series.

Test Conditions and Procedure

All tests were made with single-phase full-wave connection from 540-kva transformer bank to two 375-volt, 300-kw d-c machines connected in series. The ignitron tanks were eight inches in diameter with 6-inch graphite anodes $2^{3}/_{4}$ inches from the mercury pool. No grids or baffles were used.

In order to obtain a reasonably rapid arc-back rate for the series operation, and hence not excessively prolong the test, the water temperature was increased

Paper 41-46, recommended by the AIEE joint subcommittee on electronics, and presented at the AIEE winter convention, Philadelphia, Pa., January 27–31, 1941. Manuscript submitted November 27, 1940; made available for preprinting December 11, 1940.

J. Slepian is associate director of research and W. E. Pakala engineer for the Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.

until the arc-back rate was a value which would give rates for series operation of roughly one arc-back per day. It was found that at 700-amperes load and a cooling water-temperature range of 55 begrees to 67 degrees centigrade the arc-dack rate was satisfactory for the test. A current of 700-amperes load is 350 amperes per anode and is not too high for a 6-inch diameter graphite anode.

With conditions as stated above, the ignitrons were operated at 300 volts direct current, one at a time, until ten arc-backs had occurred for each ignitron. These data established the arc-back rate for the individual ignitron for 300-volt operation. Next, the tubes were connected in series and operated balanced (6,000 ohms across each ignitron) or unbalanced (1,000 ohms across one and 75,000 ohms across the other) at 600 volts. After completion of this series test, one ignitron was again operated at 300 volts to check if arc-back rate had changed during the experiment. During this test rates were also obtained for 300 volts by counting breakdowns, on one of the two ignitrons by means of a cathode-ray oscillograph, when the tubes were operating in series at 600 volts with voltages balanced.

The arc-back rate for 600-volt operation of *one* ignitron only was obtained by unbalancing the tubes in series with parallel unequal resistances and counting the breakdowns on the tube which carried almost all of the inverse voltage. From these measured rates at 300 and 600 volts, the arc-back rate for series operation was calculated with the assumption that the arc-back lasts for the whole half-cycle at which it occurs.

Results

The data as obtained in the experiment are compiled in table I. Several counts for the individual ignitrons were made of various durations varying from 5 to 38 minutes. The total time for counting is about the same for the 300- and 600-volt tests. From these data we find that the average time between arc-backs for ignitrons in series is 16.4 hours, when calculated from the arc-back rates of the individual ignitrons, whereas the measured average time between arc-backs is 13.75 hours. These values are for the balanced condition and check reasonably well. For the unbalanced condition, the values are seven hours as measured, and four hours as calculated. The method of calculation is described in the next section.

Discussion

When two ignitrons of the same design are connected in series, the inverse voltage will generally not divide equally between them at all times during the inverse cycle. This unequal distribution of voltage occurs only during the de-ionization time and varies from cycle to cycle. From oscillograms the inverse voltage varied from 600 to 266 volts, immediately after transition, on a single ignitron, in various cycles. This varying unbalance exists, to a continually decreasing extent, for approximately 40 degrees after transition.

To calculate the arc-back rate for ignitrons in series from the arc-back rates of the individual ignitrons, it was assumed that the arc-back cause in the individual tube exists only for the cycle considered, and that complete breakdown of the ignitrons in series will occur, if with an arc-back on one ignitron, one arc-back takes place in the same half-cycle on the other ignitron.

The calculation for the average time between arc-backs for series operation was made as follows:

If

t_3 = average time in seconds between arc-backs at 300 volts, for one ignitron
t_6 = average time in seconds between arc-backs at 600 volts, for one ignitron
f = frequency in cycles per second of power source
t_s = average time in *hours* between arc-backs for series operation

then

$\frac{t_6}{2}$ = average time for one or the other of the two ignitrons when operated in series on 600 volts

After an arc-back occurs in one ignitron, the voltage on the other anode is increased to 600 volts and its individual arc-back rate is increased. The time in cycles between arc-backs under this new condition is for one ignitron only, since we are considering that two in series are used, and we have t_3f as the number of cycles between arc-backs. The product of the above factors gives the average over-all arc-back free time for two ignitrons connected in series and in terms of hours.

$$T=\frac{ft_3t_6}{2\times 3,600}\text{ hours}$$

and for 60-cycle power source

$$T=\frac{t_3t_6}{120}$$

hours between arc-backs for the balanced condition. This equation was used to determine the arc-back free time for series operation after t_3 and t_6 had been measured.

For the unbalanced case, t_6 is used twice and since the voltage before an arc-back is practically zero on one of the

Table I

Ignitron	Resistance Across Other Ignitron	Volts	Amperes	Time of Count in Minutes	Number of Arc-Backs	Average Time Between Arc-Backs in Seconds T
3*A*48-2	None	300	700	21	6	210
3*A*48-1	None	300	700	25	7	214
3*A*48-2	None	300	700	38	10	228
3*A*48-2	6,000	300	700	19	26	46
3*A*48-1	6,000	300	700	10	5	120
3*A*48-2	6,000	300	700	10	4	150
	6,000	300	700	8	6	80
3*A*48-2	1,000	300	700	15	4	225
For 300 volts average time between arc-backs = 159 seconds						
3*A*48-2	6,000	600	700	14.5	207	4.2
3*A*48-1	6,000	600	700	15	61	14.8

3*A*48-1	1,000	600	700	7	20	21.0
3*A*48-1	1,000	600	700	10	31	19.4
3*A*48-1	1,000	600	700	16	72	13.3
3*A*48-2	1,000	600	700	12	24	30.0
Average time between arc-backs at 600 volts = 15.8 seconds						

NOTES: Measured average time between arc-backs for two ignitrons in series and balanced was 13.75 hours (Test time was 55 hours.) Calculated from data:

$$\frac{159\times 15.8}{120}=21\text{ hours}$$

Calculated with first three values of table I omitted:

$$\frac{124\times 15.8}{120}=16.4\text{ hours}$$

Measured average time between arc-backs for two ignitrons in series and unbalanced was 7 hours. (Test time was 21 hours.)

Calculated from data:

$$\frac{15.8\times 15.8}{60}=4\text{ hours}$$

Electrolytic Process of Scale Removal From Steel

H. W. NEBLETT
MEMBER AIEE

ELECTROLYTIC action is by no means new or unfamiliar. It is as old as electricity itself and has been evidenced in many ways throughout the entire application and use of electricity. One of the early applications of electrolytic action pertaining to metals was employed in the refining of copper and similar metals. Also, electrolytic action was employed in the plating of metals on surfaces requiring a high finish or protective coating, which, of necessity, should be very thin. This application is best evidenced in nickel plating and chromium plating which has been widely used for a number of years.

Electrolytic action has been in general use in steel mills and other industries for cleaning steel sheets, for example, the hot caustic electrolytic scrubbing equipment for removing oil and dirt from cold-rolled sheets. This application of electrolytic action is used in conjunction with mechanical scrubbing and brushing rolls for cleaning the sheets, the electrolytic action being a primary and the scrubbing action the secondary means for obtaining this result. It, therefore, may seem strange that this very familiar and well-known principle of electrolytic action which has been in wide and rather diversified use for so long a time has not been applied to pickling or the removal of scale from steel in a sulphuric acid bath.

The answer to this, we believe, is due to the physical and mechanical difficulties encountered when trying to apply electrolytic action in a sulphuric acid bath. There are many physical difficulties encountered when a combination of electrolytic action and sulphuric acid pickling action are combined. This can be readily understood when it is realized that electrolytic action in combination with sulphuric acid is decidedly destructive to any current-carrying metal such as nickel, copper, aluminum, or steel. Also, sulphuric acid is an active agent in decomposing some of these materials, particularly steel. Therefore, the reluctance in applying electrolytic action to the pickling of steel which involves the use of sulphuric acid, has, no doubt, largely been due to these physical difficulties encountered rather than a lack of appreciation of the benefits derived from such an installation.

Development

In the processing of flat-rolled steel, it is necessary to remove the mill scale and oxide from the entire surface of the steel which is usually produced in coils of various widths and lengths. To remove the mill scale from these coils of steel, the normal procedure is to run the strip steel through a continuous pickling line which consists of a series of tanks arranged in tandem, filled with approximately a ten per cent solution of sulphuric acid and provided with the necessary mechanism to permit the strip steel to be uncoiled and fed through the pickling line in a continuous strip, the strip being delivered at the finishing end with the scale removed by the action of the sulphuric acid in which it has been submerged. Any practical application of electrolytic action which might be used in augmenting or improving the pickling action described above, should be applied to the existing continuous pickling line and would take the position of being additional apparatus applied to this already standard equipment.

On account of the physical difficulties mentioned above, it would therefore follow that considerable experimentation would be required to develop a feasible working assembly of equipment that would have commercial application in a continuous pickling line. With this viewpoint in mind, a number of years were spent in experimenting and developing this electrolytic equipment. Early experiments were made to determine the feasibility of using either direct or alternating current, and it was found that practically equally satisfactory results could be obtained with either of these currents.

Another problem was the method of applying the current to the sheet of steel which was to be pickled, bearing in mind that since this sheet steel is being continuously fed through the pickling line, it would be necessary that any current-carrying device that made contact with the strip would have to be in the form of a roller or some similar contacting device. This, in itself, presents quite a problem, as the contacting medium would be submerged in a sulphuric acid bath and would also be carrying electric current. This naturally would result in the contact

---

tubes, it is not necessary to divide by two, as was done above. The arc-back free time for the unbalanced case will be

$$T=\frac{t_at_b}{60}\text{ hours}$$

Following table I the calculations are shown for the two cases. In the balanced case two values are given; namely, 21 hours and 16.4 hours. In obtaining the latter value, the first three values of table I were omitted. It is believed that they are high because the time ignitrons were "off the line" after each arc-back is an appreciable fraction of the operating time. This allows the tubes to cool somewhat, and higher times may, therefore, be measured. Also the unbalance due to ionization variation made these three tests of uncertain value.

When the ignitrons were connected in series and the parallel resistance across an ignitron was 1,000 ohms, an arc-back in an individual ignitron, as determined by the cathode-ray oscillograph, would continue to the end of the half-cycle at which it started. However, with 6,000 ohms an arc-back would often clear before the end of the half-cycle. This instability is characteristic of arcs when the current is limited.

Conclusions

Experiments verify that the arc-back rates of ignitrons operated in series can be calculated from their individual arc-back rates. This indicates an advantage in direct series operation of ignitrons for high voltage, rather than placing ignitrons with their associated transformers in series.

material being eaten away rather rapidly by the electrolytic action and, in most cases, would result in depositing a coating of this material on the strip steel which is to be pickled.

From experimentation, it was found that the amount of current necessary to obtain proper electrolytic action in the removal of scale was from 100 amperes to 150 amperes per square foot of the strip steel being pickled. This large amount of current, if applied directly to the steel strip, would require contact rolls at frequent intervals throughout the length of the steel strip to equally distribute the current over the entire surface of the steel. Due to the difficulty encountered in applying the current in this way, it was decided to place current-carrying electrodes in the pickle bath, these electrodes being spaced on either side of the steel strip top and bottom, the strip allowed to pass through the sulphuric acid pickling bath between these electrodes. Then, by applying alternating current to these electrodes, the current would continuously pass back and forth between the electrodes and, in so doing, would pass through the sheet, in this way setting up an electrolytic action on the sheet materially assisting in the removal of the scale. This scheme was adopted and top and bottom electrodes, spaced apart, were installed in the pickling tanks and means provided for carrying the strip continuously through the tank between these electrodes.

The next consideration was the proper material to use in forming these electrodes. Considerable experimentation was carried on in this matter and, after trying out many different materials, it was found the most satisfactory material was graphite slabs which could be made up into electrodes of any required size by the assembly of these slabs into a unit of the required dimensions. Each pickling tank is approximately 60 feet long and of a width sufficient to allow the passage of the widest steel strip, which means that these tanks, in some cases, are eight feet wide. Since it was important that the electrolytic current be, as near as possible, uniformly distributed throughout the entire length of the submerged sheet, it was decided to install a number of electrodes in each tank rather than a single top and bottom electrode which would extend the entire active length of the tank. Consequently, these electrodes were designed to a dimension that would correspond to the width of the tank and allow a multiple number of electrodes to be installed throughout the length of the tank. This resulted in a final selection of six top and six bottom electrodes being installed in each pickling tank. The actual dimensions of these electrodes, in our case, were about four feet two inches wide and six feet six inches long and were installed in a pickling line that was designed for accommodating a maximum width steel strip of 44 inches.

To further insure uniform distribution of current, means were provided for bringing current into each electrode at four points. Each pickling tank was supplied with current from two transformers, each transformer feeding one-half of the electrodes in a tank. This results in a minimum length of current-carrying conductors between the transformer and the electrodes. This is an important factor to be considered when dealing with current flow of this large amount and low voltage.

The voltage required to pass the amount of current necessary through the pickling solution varies with the strength of the sulphuric acid and the content of the iron sulphate in the solution. Therefore, transformers were provided with a five-point tap changer on the primary side which would give a secondary voltage range from 15 volts down to 7 volts. The transformers were also provided with three segregated secondary windings, each winding connected direct to one top and one bottom electrode. This was done to further insure the uniform distribution of the current to the strip steel being pickled. The lower or seven-volt tap of the transformers is used when the pickling bath is first put in use, which means that there is at least ten per cent sulphuric acid solution and no iron sulphate. As the pickling action progresses, the acid is consumed resulting in a gradual lowering of the acid in the solution. Also, since the pickling action will remove a small amount of steel from the sheet, along with the scale, there will be gradual build-up of iron sulphate in the solution. These two conditions result in increasing the electrical resistance of the pickling solution which necessitates increasing the voltage to compensate for the increased resistance. This accounts for the various voltage taps mentioned above.

It is necessary to provide some means for controlling the current supply to the electrodes which is synchronized with the feeding of the strip through the pickling tanks and so connected that the electrolytic power is on only during the operation of the pickling lines and automatically shut off each time the line is stopped. This is necessary to prevent the pickling action continuing while the strip is not in motion. If this precaution was not taken, it would result in the strip being overpickled each time the line is momentarily stopped. In addition to this automatic control, there is also provided a manual control on the pickle line operator's control pulpit board.

Electrolytic action is most active after the sulphuric acid solution has penetrated through the film of scale and has reached the steel surface of the sheet. For this reason, the first tank in a continuous pickling line is not provided with electrodes, this tank being used as a conditioning tank which will allow the acid to penetrate through the film of scale. The electrodes are installed in the second and third tanks only in which the entire electrolytic action is applied and where the major part of the scale is removed. The fourth or last tank in the continuous pickling line is used only as a clean-up tank which will remove any remaining particles of scale still adhering to the steel strip.

The terminals connecting to the top and bottom electrodes carry a heavy current and it is necessary that they be well insulated to prevent current leakage and electrolytic action on these conductors. The insulating material used should be able to stand up under the action of hot sulphuric acid and acid vapor. Good grades of rubber will give very acceptable service in acid or vapor, with temperatures not exceeding 125 degrees Fahrenheit. The temperature of the pickling solution in a continuous pickling line is approximately 190 degrees Fahrenheit. At this temperature, the life of rubber is greatly reduced, therefore it is not entirely satisfactory in this service.

After considerable experimentation, we found that a glass fabric tape, impregnated with one of the synthetic insulating compounds such as Koroseal would give very satisfactory results, and this is the type of insulation that has been employed. In some of these cases, rubber is first applied to the conductors and then the glass fabric tape applied over the rubber. In others, it is applied directly to the conductor, and both installations have proved entirely satisfactory.

The steel strip forms a catenary in each pickling tank being supported on rollers in the end of each tank and allowed to dip down into the pickling solution. When electrodes are installed above the strip, it is necessary to provide some means to prevent the steel from coming in contact with the top electrodes as it travels through the tanks. Hold-down rollers were installed at each end of the electrodes in each tank. These rollers are required to operate submerged in the acid solution and are subjected to the combined effect of hot sulphuric acid, iron sulphate, electrolytic action, and mechanical wear and shock. Materials that will stand up indefinitely in sulphuric acid, such as bronze and monel metal, will be dissipated in a very few hours when subjected to electrolytic action. Bearings have to operate submerged with no lubrication other than that of the hot sulphuric acid. These conditions are rather severe for any material that would provide a satisfactory hold-down roller.

However, a roller assembly has been developed which stands up well and gives long life and service. This consists of a roller with an extended shaft made from either carbon or a dense, compact compound using a resin base and asbestos binder. To the shaft of the roller are fitted Pyrex glass bearings. The rollers are held in position in the tanks by means of steel pipe arms which are covered with rubber, around which is applied an outer wrapping of glass fabric tape which has been impregnated with a synthetic compound. The glass bearing is fitted into a bearing housing supported by these pipes, the housing being made from the same material as the roller. This type of roller has given very satisfactory service during several years of use.

Operation

An electrolytic pickling unit, in our case, is installed on one of three continuous pickling lines.[1] This particular line is one that normally handles coils of comparatively thin gauge, narrow width, and considerable length. Due to this condition a greater speed is required on this line to produce a given tonnage in a given time than is required in the case of the other pickling lines which handle wider and heavier materials. This is the reason for the selection of this particular line to be equipped with electrolytic equipment.

The handling of coils in the feed end of a pickle line including leveling, shearing, and welding or stitching, requires a given amount of time regardless of the length of the coil. Therefore, a long coil lends itself more readily to the use of electrolytic pickling equipment than a short coil. For example, assuming a normal pickling speed of 100 feet per minute and a coil length of 200 feet: in this case, it will require two minutes for the entire coil to pass through the pickling bath. If two minutes are also required to place a new coil in the feeding equipment and perform the necessary operations such as leveling, shearing, and welding, the time of the two operations balance and there is no necessity for installing electrolytic pickling equipment in order to increase the pickling speed which is limited by the feeding operations. On the other hand, assume that the coils are available twice the length specified, or 400 feet and since the feeding time would be the same regardless of the length of the coil, electrolytic equipment could be installed to advantage, as the feeding operation would permit, in this case, a pickling speed as high as 200 feet per minute. Therefore, it is readily seen that the length of coil available has an important bearing on the advisability of applying electrolytic equipment in order to obtain additional pickling speed.

In any continuous pickling line there will be found a large variation in pickling speeds. A given line may, at times, operate at a speed of 120 feet per minute and at other times may be able to remove the scale and do a perfect pickling job on the steel at 200 feet per minute. This wide range of pickling speed is due to a number of factors, such as coiling the steel hot, or somewhat cooled before coiling in the hot mill, coils stacked hot and allowed to cool before pickling, or coils being pickled while still fairly hot, high phosphorus or high carbon steel. There are also other factors that affect the pickling speed, such as the strength of the sulphuric acid solution in all or part of the tanks, and the presence or lack of iron sulphate in the pickling tanks. Any one of these factors has an effect on the speed of pickling and when a combination of a number of these factors is present, a low pickling speed will result, and ideal conditions will naturally produce the higher pickling speeds. Therefore, these conditions also have to be given consideration in considering any means relative to increasing the pickling speed of a continuous pickling line.

Any increase in speed of pickling due to electrolytic action over what can be obtained without it results in a direct increase of tonnage from the line. This tonnage is realized with no increase in labor or overhead. The only additional cost of this tonnage is the interest on investment of electrolytic equipment, its maintenance, and the cost of the current consumed. Our experience over a number of years shows that we obtain an average increase of 35 per cent in tonnage with the electrolytic equipment over what would be obtained in this same pickling line without the use of electrolytic. The electric load for the electrolytic pickling equipment is 600 kw.

When considering the interest on investment, the maintenance, and the cost of the current consumed, it is found that the cost of pickling chargeable directly to the additional tonnage that is realized due to the operation of electrolytic equipment is considerably lower than the normal cost of pickling a ton of steel without electrolytic equipment. Therefore, under the proper conditions, electrolytic equipment shows a decided saving.

Electrolytic equipment installed on a continuous pickling line will increase the speed of the line regardless of the type of scale, the amount of scale-breaking equipment, or the grade of steel being pickled. To realize the full advantage of this increase in speed and to actually secure an increase in tonnage, the pickling line must be able to operate in the time required for a coil to pass through the pickling bath at the higher speed that can be obtained from the use of electrolytic action. Under this condition an electrolytic installation will show a good return on investment. If this condition does not exist, the time saved by the use of electrolytic equipment will be offset by the delay due to preparing a new coil for feeding into the pickling line.

The handling and feeding of coils into pickling lines is constantly being speeded up. More efficient coil handling and processing equipment is being provided by the equipment manufacturers. The time required to weld and trim coils is also being steadily decreased, all of which results in the cutting down of the time required to deliver the coil to the pickling line. This creates a condition receptive to any means that will result in a faster pickling of strip steel and electrolytic pickling equipment has a most feasible application under these conditions as a definite means of securing increased production from a pickling line.

Enclosed Bus-Bar Electrical Distribution Systems for Industrial Plants

E. T. CARLSON
ASSOCIATE AIEE

Introduction

ENCLOSED bus-bar distribution systems have come into common usage to meet the needs of industry for the greater availability of electrical power in production areas. Beginning in 1927 the automotive industry pioneered the application of enclosed bus-bar systems as a solution to the frequent recurring problem of modifying the electrical distribution system incidental to mass production changes. Since that time there has been an increased utilization of bus-bar systems by all branches of industry.

It is the purpose of the author to present in this paper a review of the fundamental electrical characteristics of such systems, discuss and describe some typical applications, and to emphasize the need for further fundamental research to meet the growing demands of industry.

The nature of industrial application requiring economy, safety, and compactness, brought about commercial designs using formed metal enclosures, porcelain or cold-molded insulating supports, and closely spaced copper and aluminum bus bars. The common industrial voltages for which commercial designs are being manufactured are: 120/240 volts, single phase, and 120/208 volts, three phase, four wire, for light; and up to 600 volts, three phase, for power.

The industrial applications of enclosed bus bars are for main feeders generally in current ratings up to 4,000 amperes, and for obtaining convenient outlets for power in current ratings, from 125 to 1,000 amperes. Both types of products are classified as "busways" in the National Electric Code, but in this paper the two types will be differentiated by the terms "feeder busways" and "plug-in busways."

While enclosing bus bars in switchboard structures, bus-bar cell construction in central stations, and interconnecting busses between equipment has been common practice for years the experience and empirical data and studies made of these bus-bar applications were not as helpful as anticipated. This is explained by the fact that these designs were of rectangular bus bars on comparatively wide spacing, and in large enclosures.

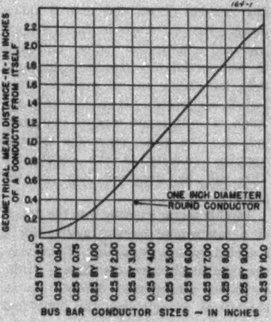

Figure 1. Geometrical mean distance of a bus bar from itself

As in all electrical distribution systems the important factors to be considered in planning a busway system are: voltage regulation, temperature rise, and mechanical design. The fundamental approach to the application of busways requires a determination of the impedance per unit length and current-carrying capacity of the selected design.

Voltage Regulation

Knowing the characteristics of a unit length of a selected design, the specified voltage regulation of a busway system, as for other distribution systems, is obtained by the usual series and parallel circuit connections.

Unfortunately, at present, specific unit length characteristics of busway systems are not as available in literature as for cable systems. One of the factors which contributes to this situation is that in meeting the increasingly exact service requirements of industry, the manufacturers have continued a process of evolution which in itself has not given encouragement to the publishing of tables and data. A second contributing factor is that in the tendency to closer and closer bar-to-bar spacing, skin and proximity effects become of increasing importance and must be studied more carefully than in the past, if exact resistance and reactance values are to be made available, for the multitude of conductor combinations now required by industry. Bar face-to-face spacings of the order of a fraction of an inch are not unlikely.

Assuming a uniform current distribution in each bar, that is neglecting skin and proximity effect, which has been rather common practice, the inductance of a rectangular bus-bar system may be determined from the scientific papers of E. B. Rosa and F. W. Grover.[3,4] This work gives the approximate self inductance of a straight cylindrical wire as:

$$L_s = 2(l)\left(\log_e \frac{2l}{\rho} - 1 + \frac{\mu}{4}\right) \qquad (1)$$

And the approximate mutual inductance between two parallel cylindrical wires as:

$$L_m = 2(l)\left(\log_e \frac{2l}{d} - 1 + \frac{d}{l}\right) \qquad (2)$$

And the approximate net total inductance per wire of a two-wire transmission line as:

$$L = 2(l)\left(\log_e \frac{d}{\rho} + \frac{\mu}{4} - \frac{d}{l}\right) \qquad (3)$$

where

l = length of wire
d = center-to-center separation of wires
ρ = radius of wire
μ = permeability of medium

When the length (l) of the wire is great in comparison with the spacing (d) the last term (d/l) of this equation may be neglected.

For a nonmagnetic cylindrical tube of infinitesimal thickness or for high-frequency circuits, where no magnetic field exists within the conductor then the second last term ($\mu/4$) may also be neglected. This condition is not always met in industrial power distribution practice and the ($\mu/4$) term (with $\mu = 1$) should remain in the equation. This term represents the self inductance due to the flux within the conductor itself and is a factor of considerable relative importance on close spacings.

Paper 41-64, recommended by the AIEE committee on industrial power applications, and presented at the AIEE winter convention, Philadelphia, Pa., January 27–31, 1941. Manuscript submitted December 2, 1940; made available for preprinting December 13, 1940.

E. T. Carlson is manager of The Trumbull Electric Manufacturing Company, Inc., Norwood, Ohio.

Grateful appreciation is extended to V. T. Chaney for his assistance in the preparation of this paper.

1. For all numbered references, see list at end of paper.

When other than a straight cylindrical wire is employed as for example the rectangular conductor in a busway, it is convenient to use modifying factors to convert the dimensions of the conductor arrangements into that of an equivalent cylindrical wire system in order to utilize the above fundamental inductance relationships.

The most acceptable modifying factors in use at the present are those based upon the concept of geometrical mean distances introduced by Clerk Maxwell.[1] Later F. W. Grover[4] published tables and data for calculating the inductance of rectangular conductors, in which the following definitions appear. "The geometrical mean distance (gmd) of a single area is that distance whose natural logarithm is equal to the average of the natural logarithm of the distances of all points of the area from each other." For a rectangular area of thickness a and width b an approximate expression of self-geometrical mean distance is:

$$R=0.2235(a+b) \tag{4}$$

where R = self-geometrical mean distance.

"The geometrical mean distance of two areas is that distance whose logarithm is the average of the logarithms of the distances of all the points of one area from all the points of the other." If D equals the geometrical mean distance of two areas and d the center-to-center distance between these areas then:

$$D=kd \tag{5}$$

or

$$\log_e D=\log_e k+\log_e d \tag{6}$$

Value of the $\log_e k$ for equal parallel rectangular areas are given in tables by Grover. Doctor O. R. Schurig[13] further simplified the solution of mutual geometrical mean distance by a graph published in his article on the calculation of inductance for rectangular bar conductors.

If the current distribution within each conductor is uniform these geometrical mean distance factors, as discussed by Rosa and Grover, can be substituted in equation 3, R for ρ, and D for d, as follows:

$$L=2(l)\left(\log_e \frac{D}{R}\right)\times 10^{-6} \text{ millihenrys per centimeter} \tag{7}$$

Note that $\mu/4$ turn does not appear in equation 7 since the flux within the conductor is taken into account in the determination of the gmd, and nonmagnetic conductors are assumed. C. C. Levy[13] discussed this point in his article "Calculation of Inductance and Current".

Examples of the geometrical mean distance factors R and D for a range of one-fourth-inch copper bus bars versus conductor spacing are given in figure 1 and figure 2 respectively. Applying these factors to equation 7 the calculated 60-cycle reactance for a wide range of one-fourth-inch bar widths is shown in figure 3. The values in figure 3 are for uniform current distribution.

It is well known, however, that the current distribution within large conductors is not uniform and therefore the geometrical mean distance factor modifications are not strictly accurate. If the current is crowded to the ends and sides of a rectangular conductor due to skin effect and if the crowding effect is made asymmetrical due to proximity effect, then this current distribution pattern is important in the determination of the flux linkages of self and mutual inductance. Further research should be encouraged to determine factors applicable to commercial bus structures, particularly for closely spaced multiple interleaved conductors. It is not only the value of inductance that is important but also the effect upon the current-carrying capacity of the conductors. This will be discussed later in the paper.

Another factor entering into the design of a commercial busway system for a specified voltage regulation is the voltage unbalance between the phases. If the conductor arrangement differs from an equilateral triangle then the individual phase voltages must be calculated and if necessary the phase conductors transposed at intervals along the busway. The problem is often identical to that of a flat transmission line. This unbalance in the induced voltages of the respective conductors is due to two factors: difference in reactance between the respective phases and the 120-degree displacement of the current in the three phases. Fortunately, it is a simple matter to make transposition in most modern busway systems and thereby attain balanced voltages.

In figure 4 are shown phase-voltage readings along an early wide-spaced (five-inch center to center of bars) high reactance, flat facewise configuration busway installation before and after transpositions were made. Present-day closely spaced designs would produce the same relative characteristics, but with voltages of much improved regulation.

Power-factor correction static condensers are often located along the lines of a busway system to take full advantage of improved voltage regulations along with power-factor correction.

In these early systems as well as in many installations of today, reactance plays a dominant part in the impedance drop, while as spacings are made closer, the resistance component becomes increasingly important and may even itself become dominant. Here again, the importance of skin and proximity effect enters into voltage regulation calculations, this time by increasing the a-c resistance.

Current-Carrying Capacity

While skin effect causes a higher density in the outside periphery of a conductor, proximity effect has the tendency to crowd the current to the outside when currents flow in the same direction in adjacent conductors and to the inside when currents flow in the opposite direction in adjacent conductors. In certain cases, therefore, proximity effect may in combination with skin effect, actually cause a better distribution of current and, therefore, a lower a-c resistance than results from skin effect alone. On the other hand, these two effects more often combine to produce a considerably greater a-c resistance. Tests have shown this increase in resistance to be very significant. A more comprehensive knowledge of these combined effects will prove beneficial in the accurate establishment of the current ratings of bus-bar systems for a given temperature rise. Limited investigations seem to point to the importance of symmetry where several conductors are connected in parallel.

When bus bars are spaced closely, phases connected in parallel and interleaved as in figure 5, more research and study will be required before an accurate prediction can be made of the system's voltage regulation, power loss, and current-carrying capacity.

It is present commercial practice to rate bus systems arbitrarily on the basis of 1,000 amperes per square inch, despite the fact that this system of rating does not result in a uniform temperature rise for the respective sizes at rated load. Progress is being made, however, toward a more accurate rating of the bus systems through the co-operation of manufacturers with the underwriters. In the meantime, the manufacturers simply provide the necessary capacity to carry the load for the specified temperature rise.

Another and very important factor in the modern busway system is the design of its protective enclosure. The present practice is to make these enclosures of steel for ratings below 1,500 amperes, and of nonmagnetic material for high-current ratings.

Housings of nonmagnetic materials are often preferred to steel for certain high-current rating designs because of the high-flux densities and eddy currents induced in the steel housings which give rise to excessive temperature and voltage drops.

Various means are employed for ventilating the housing and cooling the enclosure by convection, but in general, the enclosed system will not have as high a current-carrying capacity for a given temperature rise as will bars in the open air. Industry, of course, realizes this

situation and accepts the lower capacity of the enclosed system because of its obvious other advantages. The actual rating of an enclosed system in the final analysis, probably, will be based upon tests of the particular design. In general, it is the same problem as encountered in the operation of a number of cables in a duct enclosure. An example of the carrying capacity of some typical busway systems is shown in figure 6.

Applications

It is interesting that the earliest industrial electrical distribution systems had open feeders extending the length of the plant, with ceiling-mounted link-fuse protection of tapoffs for individual power loads, similar to the fundamental concept of modern busway systems. The fire and personal injury hazards of the materials then available brought about the alternative practice of radiating conduit and wire feeders from a main switchboard or from several subdistribution centers.

The radial system met industry's needs through the early decades of this century, but with the advent of mass production, individual motor drives, expanding and changing load centers, the static nature of the radial system often resulted in overloaded feeders and equipment, poor voltage regulation, and costly rearrangement expenditures. A system which would provide the same convenience for power in industry as plug receptacles do in the modern home, became industry's demand.

Plug-in Busways

This need of industry for a greater convenience of power is being met by manufacturers with a system of power and light plug-in devices which engage bus bars supported within a metal enclosure.

The complete system for an industrial plant usually consists of a number of overhead parallel busway runs located according to machinery concentrations, plant conditions, and column centers. These bus structures are usually located overhead and supported by building structural members. An exception to this method of supporting the busway is shown in figure 10 which is a photograph of an installation in a high bay crane area where suspension means of support could not be used.

Connections are made to the busway circuits by the insertion of combination plug-in switch and protective devices at such points as to provide the most economical branch circuit layout. A section of a typical busway run with plug-in device in position is shown in figure 8. The arrangement of bus bars and construction details of a typical busway type of enclosure with its insulator assembly is shown in figure 7. Branch circuits are extended from the plug-in protective device by the customary wiring method to the individual power equipment drives or distribution centers. Such an example is shown by the photograph in figure 11.

The growing need for the installation of static condensers to correct for low power factor has led to the design of plug-in capacitors which correct for power factor and improve the voltage regulation on the busway. The location of these capacitors, of course, depends upon the characteristics and distribution of the load, but as a rule, a location near the load end of the busway provides best results. A photograph of a typical

plug-in capacitor is shown in figure 9.

The common industrial application of busway plug-in systems is to 440-volt, three-phase, three-wire, 60-cycle a-c power distribution, although there is an increasing acceptance of the plug-in busway for three-phase, four-wire combination light and power systems. Where light is supplied from a busway it is general practice to extend conduit and wire circuits from plug-in equipment to lighting distribution panel boards or transformers. Where there is a need for an even more flexible supply of power to portable tools, such as along an assembly line, it is the practice to install a trolley collecting device supported on a track which is an integral part of the bus-bar enclosure.

Figure 11. A close-up view of layout, figure 10, showing protective devices and branch motor circuits

Plug-in busways may be supplied with power directly from distribution centers, by conduit and cable wiring methods, or by a feeder type of busway.

Feeder Busway

Feeder busways differ from the plug-in type in that they are generally of higher current-carrying capacity and are not provided with plug-in outlets. The usual method of tapping off loads from feeder busways is by bus-bar connections or conduit and wire. The conduit and wire branch feeder connections are generally made through metal enclosures attached at the joint sections.

A layout of a typical feeder and plug-in busway system is shown in figure 12. In this figure a section of feeder busway extends from the transformer supply to the main protective device. From the protective device the feeder busway extends the full length of the plant to supply the individual plug-in busway branch runs. Because of the high-capacity requirements of feeder busways it is often necessary to arrange many bus bars in parallel and to interleave the phase conductors to obtain a low reactance. Such a feeder busway is shown by the photograph in figure 13. A multitude of arrangements may result in the application of feeder busways to and from

Figure 13 (left). Commercial design of interlaced feeder busway with steel backplate and ventilated aluminum enclosing channel

switchboard, as is typified by figure 14.

Feeder busway systems, particularly for three-phase, four-wire light and power distribution, have been successfully used as risers in buildings having many floors. The load requirements of each floor are tapped off the busway and distributed through panel boards or plug-in busway.

A comprehensive treatment of the general problem of welding applications as reported by the AIEE subcommittee on power supply for welding applications,[16] is published in the May 1940 issue of Electrical Engineering. This activity has stimulated the development of feeder busways to provide designs for improved voltage regulation on welder service. These improved designs will be characterized by close phase-to-phase spacing of bus bars and convenient methods of extending conduit and wire feeders from the busway to welding machines.

Lead Storage Batteries in the Transportation Field

ROLAND WHITEHURST
MEMBER AIEE

Synopsis: A review of storage battery applications in the railroad, motor bus, and aircraft transportation fields. Historical notes are recorded of events in the development of gas and Diesel-electric rail cars and Diesel-electric locomotives, especially as those events relate to storage batteries. Similar treatment is given to other battery applications—car lighting, air conditioning, busses, and aircraft. The changes made in the construction of batteries for these services are described. Physical and electrical characteristics are emphasized where they have a bearing on the application.

Introduction

ELECTRIC starting of automobile engines is taken for granted until you have to crank one by hand. The drivers of 24,000,000 automobiles and 4,000,000 trucks which operate today, have little appreciation of the job done by storage batteries. Probably only those engineers intimately associated with the application of storage batteries in the transportation industry know of the degree to which storage batteries have performed much larger jobs. For example, they are used on all commercial air transports; they furnish the power to crank gas and Diesel engines on over 1,500 rail cars and locomotives, and on over 138,000 busses. Storage batteries also help to electrically air condition over 12,000 railway passenger cars, and they insure power supply to 40,000 signals used by the railroads for safe operation of trains. There are few who are familiar with the changes in design which were necessary to fit storage batteries to the peculiar requirements of certain transportation applications.

I. Railroads

A. ENGINE CRANKING

1. *History.* At the beginning of the century a self-propelled rail car was introduced in which the electric driving motors received their power from a storage battery operating in parallel with a generator driven by a gasoline engine. The storage battery took care of peak loads and the generator furnished the average power required.

The forerunner of the present-day gas-electric rail car using variable voltage control appeared first in 1905. The engine was started by compressed air. About 1910, a small six-volt storage battery was added to furnish ignition current.

In 1905 a mechanically driven car known as the McKeen car was also introduced. Following Mr. Kettering's success of starting automobile engines by an electric motor in 1911, the idea was expanded to include the larger size gas engines then being applied to rail cars. Usually a 12-volt 120–160 ampere-hour storage battery served for cranking and lighting purposes.

There was a decided lull in the development of rail cars between 1912 and 1924. In the latter year an improved design of gas-electric rail car was introduced in which a 32-volt 215 ampere-hour storage battery was used for engine cranking, car lighting, and generator excitation. Thereafter a rapid expansion in the number of gas-electric rail cars took place. In Europe, on the other hand, gasoline was expensive and difficult to obtain, so that greater efforts were directed toward Diesel-powered rail cars.

In 1923 a Diesel locomotive, employing electric drive, was built in Europe. Starting windings were provided on the generator and the Diesel engine was cranked by the storage battery in this manner for the first time.

In February 1924 a 300-horsepower Diesel electric locomotive was placed in service in the United States. The engine was started by compressed air and a 16-cell 108 ampere-hour storage battery furnished current for excitation, control, and lighting. Two years later a 64-cell battery of the same capacity was added for engine cranking. Soon thereafter the cranking, excitation, control, and lighting circuits were connected to a common 56-cell battery.

In 1933 the Diesel-electric locomotive entered the high-speed passenger train field with a single 600-horsepower engine using a 64-volt 425 ampere-hour battery. Some of the present 6,000-horsepower locomotives are composed of three cab units operated by multiple-unit control. Each cab unit has two 1,000-horsepower engines and a 64-volt 425 ampere-hour battery.

In the early days of electric cranking of engines, it was the practice of locomotive manufacturers to use empirical formulas to determine the torques required to "breakover" and "fire" Diesel engines. By combining this information with the characteristics of the generator starting winding and a battery, it was possible to arrive at a suitable size of storage battery. Experience taught them that a battery sufficiently large to perform the cranking duty would adequately take care of the other electrical duties assigned to the battery. As engines grew larger it was desirable to re-examine the cranking requirements. Oscillograms were obtained of the starting conditions and the information used in a manner similar to that described in a paper delivered before AIEE at its 1940 summer convention in Swampscott, Mass.

2. *Adaptation of Storage Batteries.* Although the eight-hour battery capacity rating is traditional, it is of little value in Diesel cranking service, because, in this service, the battery must (1) "breakaway" the engine from standstill and (2) quickly bring it up to "firing" speed.

Condition (1) is essentially one of torque, and torque is proportional to amperes. The high breakaway torque has, in practice, required batteries to discharge at rates up to approximately their one-minute rate. To provide the necessary high-current rates, it is desirable to keep the internal resistance of the battery at a minimum and the current-carrying parts of adequate cross section. Condition (2) involves delivery of current for a reduced torque and at a voltage that will give speeds somewhat in excess of the minimum speed required for firing in order that the engine may fire quickly.

In order to satisfy both conditions, it has been found advisable to use multiple current-carrying posts, and to use copper inserts in these terminal posts and in the lead intercell connectors. Also cells were arranged in the trays in such a way as to make the intercell connectors as short as possible and the connectors were lead-burned to the terminal posts in order to reduce contact drop.

Figure 1 shows a typical characteristic of a battery used to crank a 900-horse-

power Diesel engine. Figure 2 shows the accumulated horsepower of Diesel-electric locomotives in the United States.

B. Car Lighting and Air Conditioning

1. History. The first attempts at car lighting by electricity were made in 1881 and continued in an experimental stage for about ten years before practical results were obtained. The Planté type of storage battery which had been developed in 1860 was the first to meet car lighting requirements successfully. The Faure or pasted-plate type of battery was developed about 1881, but was not used in car lighting service until many years later because the earlier designs were not rugged enough. In the early types of car lighting batteries the elements were installed in alloy containers, two containers being grouped in a wooden tray. Porcelain rests supported the elements at a sufficient height from the bottom of the cell to provide space for sediment accumulation. Later, rubber jars were substituted for the alloy containers. In either case alloy or rubber covers were used.

Railroads operated well-equipped battery repair shops and regularly examined car lighting batteries, removing sediment, changing separators, and renewing plates when necessary. It was not uncommon to obtain a life of 20 years from negative plates, requiring three or four sets of positive plates. Gradually this practice of rebuilding batteries was discouraged by the railroads in favor of using a "single life" battery whose separators and plates would wear uniformly. The trend was definitely away from the Planté type and toward the lighter weight pasted-plate type battery.

In 1927 the first air-conditioned railway passenger car, a Pullman sleeping car, was placed in experimental service. Three years later the idea was tried by several railroads, and it was enthusiastically accepted by the traveling public. The rapid expansion of air conditioning on railroads in the United States is shown in figure 3.

Five different types of air-conditioning systems are used by the railroads. They are distinguished chiefly by the manner in which refrigeration is produced, and are separated as (1) ice activated, (2) mechanical compression with the compressor driven by an electric motor (electromechanical), (3) steam ejector, (4) mechanical compression with the compressor driven directly from car axle (direct mechanical), and (5) mechanical compression with the compressor driven by an internal combustion engine. The refrigeration capacities available for railway passenger cars vary from three to nine tons per 24 hours.

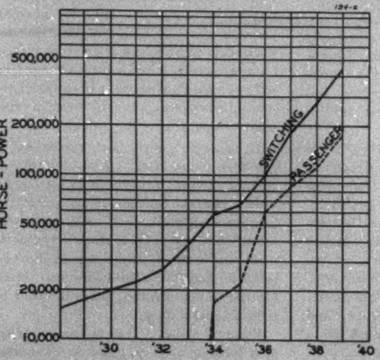

Figure 2. Cumulative horsepower of Diesel-electric locomotives in U.S.A.

Before describing the increased power requirements brought about by the addition of air conditioning, it will be helpful to refer to table I which shows what the Association of American Railroads set as a standard for storage battery and generator capacities when applied to *car lighting* service. The AAR is undertaking a study to make comparable recommendations for combined air conditioning and car lighting service. During the past three years better illumination has been emphasized and has been adopted in varying degrees by different railroads. Attractive interiors were provided on newly designed cars with new and improved types of lighting fixtures which meant further increases in intensity at the lighting source. In some of the latest cars the lighting load has reached a total of 170 amperes at 32 volts.

These heavier lighting loads plus any additional amount demanded by air-conditioning equipment are taken from the storage battery during periods of a train run when the train is operating below the cut-in speed of the generator and, in some cases, when the car is being precooled prior to a run. This was responsible for increasing the size of the storage battery to from two to four times that previously used in car lighting service alone. The capacity of generators was also increased to correspond with the increase in load. Experience indicates that a minimum generator capacity of 166 per cent of the connected load should be provided. While this ratio may seem somewhat high for new cars in long runs or express service, it is only a matter of time when such new cars are relegated to local or semilocal service in which higher generating capacity is desirable.

2. Air-Conditioning Power Requirements. The electric load in an ice activated system consists of 0.5 kw to the cooling coil fan and 0.75 kw to the cold water circulating pump or a total of approximately 38 amperes at 32 volts. In the majority of cases, one four-kilowatt axle-driven generator has sufficed. Referring to table II, it will be noted that the 600 ampere-hour size battery is the most popular. However, the lighting load and the type of car has influenced the choice of this capacity more than has the air-conditioning load.

The greatest range in power requirements occurs in the electromechanical system of air conditioning. Refrigeration capacities vary from 3.5 to 9.6 tons. In the vicinity of the six-ton rating, the total power requirements may vary from 8.5 kw to 12 kw. The motor driving the compressor requires approximately 93 per cent of this total, the remainder being consumed by evaporator fans, control, and in some cases, condenser fans. Comparisons made of various manufacturers' equipment rated around six tons showed that an average of 1.75 kw per ton of refrigeration was required, or a total of 10.5 kw at six tons. This represents an average increase above car lighting requirements of about 330 amperes at 32 volts. Generator capacities were raised to 15 kw, then to 20 kw, but it was not practical to increase the storage battery capacity correspondingly. Space and weight are limited and the problem became one of how much capacity could be installed in the standard AAR battery box. The electromechanical system of air conditioning imposed the greatest demands on the storage battery and therefore provided the greatest influence in the change of storage battery design. One of the large eastern railroads, a pioneer in the use of the electromechanical system, set 1,000 ampere-hours capacity (32 volts) of storage battery as a goal for manufacturers to strive to build and install within the standard compartment.

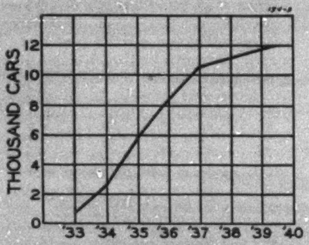

Figure 3. Air-conditioned railway passenger cars in U.S.A.

The power required in the steam ejector system is second to that of the electromechanical system. The total load amounts to approximately 104 amperes at 32 volts and consists of the condenser fan, condenser pump, cooling coil fan, and cold water pump. Referring to table II, it will be noted that the majority of installations use approximately 850 ampere-hour storage batteries. Generator capacities for this type of system vary from $7^1/_2$ kw to 10 kw, the latter size being found in most cases.

The direct mechanical system has the lowest electrical requirement and therefore the least effect on the size of battery installed. The 550 ampere-hour capacity was the most popular because one of the largest operators of air-conditioned cars chose it as their standard. It is estimated that the bulk of installations from 1938 to date used 600 ampere-hour batteries.

One manufacturer has developed an internal combustion engine which uses bottled propane for fuel and can be adapted to drive either a compressor or a generator. As an engine generator it removes the load from the car axle and there is no change in electric power used. When the engine is directly connected to the compressor, however, the electric power requirements drop to that of the direct mechanical system. Most of the installations of this type of system have been made on railroads in the Middle West and the preponderance of 450 ampere-hour storage batteries coincide with the standard size of car lighting battery of two large users.

3. Storage Battery Developments. The life of Faure or pasted plates depends on the cohesion of the active material and its retention by the grid structure. These are influenced by the porosity of the active material and by the shape of the grid section. Thus a soft porous plate will give higher capacity in its early life, but has a tendency to shed the active material. Hard dense plates do not give as much capacity initially, but are slower to "soften" with work and age, and consequently will give much longer life. It is of prime importance that plates be uniform because they will be "teamed" as groups in a battery which must work and wear evenly. To accomplish uniformity manufacturers must control closely not only the quality of materials used but also the physical conditions of manufacture, such as temperature, time and humidity, that exist while making and processing the plates.

A retainer or envelope is placed about the positive plate for a twofold purpose: (1) to hold the oxides in place mechanically and in contact with the grid, and (2) to delay oxidation of the separators. In one case the retainer has been a thin sheet of finely slotted rubber. In another case a modified Faure plate was made by enveloping a series of grid pencils with cylinders of active paste material and each cylinder encased in a finely slotted rubber tube. In a third case the retainer has been a thin mat of fibrous material usually made of spun glass.

Plate separators act as electrolytic diaphragms which permit current to pass freely between the plates but prevent any migration of dislodged active material from one plate to another of opposite polarity which might bridge and cause a short circuit. In some respects wood is an excellent material for separator use but its disadvantage lies in its inability to withstand high temperatures. In 1933 a new separator was developed from liquid latex, or the milk of rubber as the base. This material when compounded with certain other materials and vulcanized forms a microporous diaphragm which successfully withstands oxidation and heat. In another case a similar separator was obtained by vulcanizing a mixture of crude rubber and sulfur with certain other materials, the latter being dissolved out to form the minute pores.

The trays used for car lighting batteries were usually made from oak, maple, or long-leaf yellow pinewood, painted with an asphaltum paint and then immersed in a molten wax compound. Hard rubber jars held the elements and electrolyte, and the wood trays became the supporting structure for two or more jars. Such an assembly occupied more space and weighed more than a self-supporting container. Another disadvantage occurred when high temperatures melted the wax coating and exposed the wood to decay. A self-supporting rubber monobloc container was developed in 1935. This container saves space, is not subject to decay, and possesses a remarkable quality of toughness. It is handmade from rubber compounds which contain relatively high percentages of rubber. One type of container is made up of two dissimilar rubber compounds—one resistant to heat, the other resistant to shock—calendered together and handwrapped about mandrels, and then vulcanized. There are now over 50,000 of these monobloc containers in service.

Table I. AAR Recommended Battery and Generator Capacities for Railway Car Lighting

Class of Service	Amperes Load	Battery Capacity Range Ampere-Hours Min	Battery Capacity Range Ampere-Hours Max	Generator Capacity (Kw)
Official, sleeping, parlor, mail, and dining cars having heavy lighting loads or severe operating conditions	50	350	600	4
Mail, dining cars, etc., where the lighting loads are not so heavy or the operating conditions so severe	35	300	350	3
Coaches, passenger-baggage cars, baggage cars under average operating conditions	25	200	300	2
Same cars as next above operating in slow speed branch line or local service	25	150	225	2

*This also includes all installations made prior to 1933.

In order to minimize IR drop, number 0000 cable composed of upward of 5,000 strands of wire is used to connect adjacent battery trays where 800 to 1,000 ampere-hour batteries are used. Extra flexible cable is required for the larger batteries which practically fill available compartment space. One alternative for reducing the large cable requirement has been adopted by several railroads when the system voltage was doubled to 64- and 32-cell 500 ampere-hour or 600 ampere-hour storage batteries used. In another case one railroad equipped 115 cars with 110-volt lighting and air-conditioning systems.

Table III compares a 300 ampere-hour Planté car lighting battery of 1920 with a typical car lighting battery as used today. Today the railroad can obtain a 300 ampere-hour car lighting battery that will occupy one-third the volume of the 300 ampere-hour Planté battery used in 1920; it will weigh only 40 per cent of the 1920 battery; it will cost only 70 per cent as much, and will have a longer life expectancy.

For heavy duty air-conditioning service, it is now possible to install a 16-cell 1,000 ampere-hour battery in the same size compartment which formerly held 16 cells of a 400 to 450 ampere-hour battery. The increased cycling of the battery together with the heavier loads mean higher operating temperatures which are now permissible because of the present development of plate separators. Tightly packed elements permit today's storage batteries to operate throughout their life without mechanical failure of the separators which otherwise might be caused by vibration. Compared with the 1920 300 ampere-hour car lighting battery, the railroad can obtain today an air-conditioning battery of $3^1/_2$ times the capacity installed in the same size compartment, weighing only 25 per cent more, costing only 70 per cent more, and, when used on a load ten times greater, having a life expectancy equal to the 1920 battery.

C. STREET RAILWAY PCC CARS

Several papers have been presented to the Institute on "Presidents Conference Committee" street railway cars. Today there are about 1,500 of these PCC cars in service in this country, each of which is equipped with a 16-cell 55 ampere-hour storage battery. The battery is connected across a voltage-regulated motor-generator set. The loads on the battery circuit include magnetic track brakes, control, step treadle equipment, headlight, stop lights, marker lights, passenger signal system, instrument panel, and sometimes fare box lighting. The total load may reach a maximum of 75 to 80 amperes while magnetic track brakes are energized.

II. Motor Busses

Passenger busses are classified along with passenger automobiles and trucks as automotive equipment. While technical discussions on this subject are normally conducted by SAE, a few remarks on the application of storage batteries to busses may be appropriate in view of their widespread use for commercial transportation.

The year 1911 marked an important milestone in the development of automotive equipment, for it was in that year the electric starting motor for gasoline engines was introduced. Prior to that time all automotive engines were cranked by hand. A campaign for better illumination of bus interiors brought greater lighting loads and in order to minimize voltage drop, a 12-volt circuit was standardized. Battery sizes increased with the change in lighting load from 13 plates to 17 plates and in some cases up to 25 plates. Bus battery plates were thicker than those used in automobile batteries because busses operated in more continuous service and under more adverse conditions.

In railway, marine, and stationary battery applications it is customary to rate the batteries on an eight-hour basis, whereas in bus service it is customary to rate them on the four-hour basis. The capacity of bus batteries was at one time selected on the basis of a six-hour reserve for the operating load exclusive of the starting motor. From experience it was found that a size capable of supplying this reserve was ample for any starting conditions normally encountered. Today the electric loads on busses reach values of 65 amperes at 12 volts and the size of battery recommended is one that will carry the load for four hours.

Fuel economies associated with Diesel engine operation helped to bring about the development of the small high-speed Diesel for bus and truck service. Two six-cell bus-type batteries are connected in series for 24-volt starting and then paralleled for 12-volt lighting.

In 1935, trolley busses made their appearance with 12-volt storage batteries used for control and lighting purposes to avoid high trolley voltages within the bus.

III. Aircraft

Military planes have been responsible for most developments of aircraft electric equipment. The Liberty motor in service during World War I was the first to use a storage battery for ignition. The battery weighed 11 pounds and contained four cells with seven plates per cell.

By the end of that war, military planes were being equipped with direct drive starters. The cranking batteries were usually six-cell, 20, 35, or 70 ampere-hours capacity (five-hour rating). Similar equipment was used by mail and commercial planes about 1925.

The inertia starter, brought out in 1925 plus an improved design of generator, hastened the adoption of electric starting of aircraft engines. Because of the importance of weight, very thin pasted-plate batteries were developed for aircraft service. The plates used in the first Army plane batteries were only 0.05 inch thick. As airplane flights became longer, swifter, and more severe on auxiliary equipment, it was found desirable in 1930 to increase the plate thickness by 50 per cent.

Table III. Comparison of 1920 and 1940 Typical Car Lighting Batteries

	1920	1940
8-hour capacity	300 A.H.	300 A.H.
No. cells per tray	2	4
Tray material	Wood	Rubber monobloc
Tray dimensions		
Length	$24\frac{3}{4}$"	19
Width	11"	$9\frac{3}{4}$"
Height	$19\frac{1}{4}$"	$19\frac{3}{4}$"
No. trays per battery	8	4
Total battery volume	24.26 cu. ft.	8.5 cu. ft.
Total battery weight	2,600 pounds	1,010 pounds
Purchase price	100%	70%
Expected life	5 years	7 years

It is interesting to note that a modern passenger airplane's intermittent load on a 12-volt circuit may total 225 amperes. During a $5\frac{3}{4}$-hour night flight in the winter, a typical example of the electric load would be about 490 ampere-hours at 12 volts normally supplied by two 50-ampere generators in parallel. The six-cell 13-plate battery used in this example weighs 78 pounds, has a capacity of 88 ampere-hours (five-hour), and occupies a space 14 by 7 by 11 inches high. It would be capable of carrying 150 amperes for 18 minutes or 200 amperes for 12 minutes.

The large 21-passenger skyliners have two 850-horsepower engines, two storage batteries like the one described above, and means to use either battery or both connected in parallel. The latest Stratoliners have four 1,150-horsepower engines and two 24-volt 50 ampere-hour batteries. The very large engines are using the direct drive starter again rather than the inertia starter. To conserve battery capacity, the heavy duty cranking prior to a plane's departure from an airport, is taken care of by a portable ground-cranking battery which is wheeled under the plane.

Future Developments

Thought and study is being devoted to heating railway passenger cars electrically. Air conditioning includes the proper control of temperature and humidity of the air during winter months as well as summer months. At least three manufacturers are now developing engine-driven equipment that will heat, light, and air condition a car. On one system it is planned to generate 220 volts three-phase, alternating current for heating and air-conditioning purposes. A 64-volt 150 ampere-hour battery will be used to crank the engine, provide the control circuit energy, and light the car. The battery will be charged from the exciter. The adoption of 64 volts direct current for lighting permits the use of a recent development—the fluorescent tube which operates at 60 volts direct current from the battery circuit without transformation of energy. Thus the engine may be shut down temporarily without affecting the source of illuminating power.

In view of the large quantities of rubber materials now used in the production of lead storage batteries, some concern is felt for the continuity of crude rubber supplies. While numerous synthetic rubber substitutes are now being marketed, little enthusiasm can be expressed for any one of them at this time, because experience has taught us to be wary of any possible unhappy union of storage battery electrolyte with an element from the synthetic material. Research is now directed toward the use of some of the newly developed plastics, and it is predicted that they will find increased use in the storage battery industry.

Bushing and Associated Insulation Testing by the Power-Factor Method

C. C. BALTZLY
MEMBER AIEE

E. L. SCHLOTTERE
NONMEMBER AIEE

I. Introduction

THE periodic cleaning, inspection, and testing of equipment plays a very important part in obtaining service continuity. The cost of the labor and equipment involved in locating and eliminating defective apparatus by the above procedure may well be charged to that hypothetical account known as "preventive maintenance." The economics of the procedure, however, must be governed by the results obtained.

For many years, bushings and associated insulation such as the internal parts of circuit breakers and windings of instrument and power transformers were tested by methods which were frequently unreliable, inadequate or of a destructive nature. During the past ten years the a-c test known as the power-factor method of insulation testing has gradually been replacing the former methods used for periodic checkup. It is also gaining recognition as one of the requirements in the acceptance tests made on certain types of new equipment.

The results obtained by Philadelphia Electric Company, using the power-factor test method for approximately eight years, has warranted the continuation of a periodic test program. A few bushing failures still occur but they are confined mostly to the low-impulse type of design and cannot be anticipated by any nondestructive type of test. A centralized bushing repair shop has provided the means for salvaging bushings and other equipment at a reasonable cost, for years of useful life. All equipment rejected by test has, upon investigation, disclosed faulty insulation which warranted its removal from service.

II. Scope of Testing

The power-factor method of insulation testing was first used by this company in 1933, and was confined primarily to outdoor oil circuit breaker bushings. The Doble type *I* tester was used for this work and the results of the first three years' work has been previously summarized.[1]

In 1936, a second type *I* tester was placed in service and the range of testing was broadened to include power and instrument transformers and lightning arresters. With the further development of test equipment by the Doble Company, the two type *I* sets were replaced in 1939, by an *I*-10 and an *I*-30-150 set. A type *U* set was also obtained for use in the bushing repair shop in 1938.

The power-factor testing outlined for each year is as follows:

(*a*). Outdoor oil circuit breakers.

(*b*). Power transformers.

(*c*). Instrument transformers, alternated every other year with station-type lightning arresters.

(*d*). Cold collar and/or hot collar tests on all bushings containing a compound filler.

(*e*). Hot-guard test on all draw-lead type transformer bushings.

(*f*). Oil samples on all power transformers.

(*g*). Oil samples on all oil circuit breakers and instrument transformers as necessitated by over-all test results.

(*h*). Spare bushings.

(*i*). Follow-up field tests as required.

(*j*). Indoor oil circuit breakers during winter months.

(*k*). Follow-up and acceptance tests on all equipment reconditioned in the shop (by the shop force).

(*l*). Acceptance tests on all new bushings.

(*m*). Base checks on all new power transformers.

III. Field Testing

The technique of field testing has been very thoroughly covered in previously published articles,[2–7] listed in the bibliography and will, therefore, not be repeated.

It requires about two years' work to completely cover the outdoor equipment on the Philadelphia Electric Company system. However, the most important locations are tested yearly. A tentative schedule allocating the work is made up each year as a guide for the field test men. Due to its larger capacity, the *I*-30-150 set is used for practically all power transformer tests.

In order to insure proper follow-up of rejected equipment, a 3- by 5-inch card is used for each piece of equipment tested (bushings are included with the circuit breaker) and the condition of the equipment is noted as satisfactory, follow-up, or rejected. These cards are sent daily to the superintendent in charge of the location where the testing is being done. A summary sheet of all rejected equipment is made up weekly and forwarded to the general superintendent of the respective division. When the testing at a specific location has been completed, a copy of each data sheet, approved by the supervisor in charge of the tests, is forwarded to the superintendent of that location for reference and file.

Field testing is seldom carried on when the ambient temperature is lower than five degrees centigrade or when the humidity is high enough to cause considerable surface leakage. The rating schedule for bushings and instrument transformers at 20 degrees centigrade ambient temperature is given in table I.

An arbitrary value of five per cent maximum at 40 degrees centigrade has been established for power transformers although it is still a moot question as to the satisfactory condition of the winding insulation when lower than one per cent especially when subjected to a dry-out run. The current and watts loss readings must also be carefully analyzed and due consideration given to the type of insulation and winding construction before the unit is accepted or rejected.

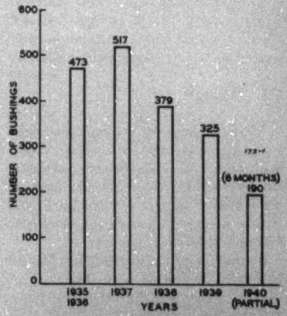

Figure 1. Bushings reconditioned in the shop. Total for 5 1/2 years = 1,884

Paper 41-72, recommended by the AIEE committee on standards, and presented at the AIEE winter convention, Philadelphia, Pa., January 27–31, 1941. Manuscript submitted November 22, 1940; made available for preprinting December 21, 1940.

C. C. BALTZLY is general superintendent, station operations, Philadelphia Electric Company, Philadelphia, Pa. Mr. SCHLOTTERE is also with this company.

Figure 2. Bushing reconditioning report

Considerable work has been done since 1937, in the investigation of station-type lightning arresters such as the oxide film, type *BO;* auto-valve, type *SV* (disk and porous block construction); and Thyrite, types *LAIB* and *LAIY.* Arbitrary values obtained by comparison and internal investigation of units are being used rather successfully but it is hoped that compilation of further data will offer a more direct solution of the problem.

Wood members, insulators, and the porcelain-tube type of wall bushings are analyzed on the basis of current and watts loss data rather than by power factor. Satisfactory oil is found to be one per cent or under. Above that value other tests, such as dielectric, acidity, color, etc., are made before rejection.

IV. Test Results

A. Bushings (Field Test)

For the three-year period 1933–35 inclusive, about 6,000 bushings were tested. Since that time approximately 4,000 bushings are tested in the field each year. Table II indicates that 1,493 bushings of various types and voltages have been rejected in the past five years. This represents about 7.5 per cent of the total number tested. It should be noted that the rejection of indoor bushings during the past four years accounts for approximately 30 per cent of the total number rejected. The rating schedule was arbitrarily lowered for the indoor bushings on the basis that they would only be tested at four- or five-year intervals.

Table III presents a breakdown of the reasons for rejection. Power factor accounts for 65 per cent of the total and compares with the results of the 1933–35 period[1] of 63.8 per cent. However, in order to make a fair comparison, the indoor bushings must be deducted which would then approximate 35 per cent instead of 65 per cent. This indicates that the trend is downward which should be expected in order to justify the expenditures made in replacement and reconditioning. Moisture accounts for more than 90 per cent of the rejections by power factor.

The 17 per cent rejection due to oil migration and compound leaks is confined largely to transformer bushings and is usually determined by inspection rather than test. The "miscellaneous rejections" is somewhat high (14 per cent) due to placing a number of multipiece porcelain bushings which were rebuilt with single-piece porcelain, in this classification. The percentage of miscellaneous rejections would be in the order of three per cent or less if this modernization item were omitted.

B. Bushings (Shop Test)

The bushing reconditioning shop was started in 1935. Figure 1 shows the number of bushings reconditioned since that time. The total of 1,884 consists of all types of bushings ranging from 7.5 kv to 73 kv. The first year was devoted to the training of personnel, experimentation with materials and methods, building special racks, providing special tools, etc. Larger ovens were designed and installed in 1936, so that large-scale production did not get under way until 1937. During the period 1935–37, it was necessary to assign a field man for shop testing several days each week. This decreased the amount of outdoor testing possible and at the same time proved to be inadequate to meet shop requirements. In 1938, a Doble type *U* set was provided. The shop men now average about 3,000 tests (follow-up, acceptance, etc.) per year.

All bushings (15 kv to 73 kv) after being reconditioned are subjected to a one-minute hold voltage test using the values recommended by the manufacturer for present-day design. This test has resulted in the elimination of a few older type bushings which probably would have failed in service due to faults which could not be determined by a nondestructive test.

Figure 2 is the form developed for detailing the shop history of bushings and instrument transformers. Figures 3 and 4 show the front and rear view of the type *U* tester used in the shop.

C. Transformers

During the past four years, 493 power transformers have been tested. This group of transformers covered a voltage range from 13.2/2.3 kv to 220/66/13.2 kv and a capacity range of 100 kva to 43,333 kva single phase and 1,000 kva to 20,000 kva three phase. All low-voltage windings (2.3 kv and 4 kv) are tested at 5 kv, the higher voltage windings at 10 kv. From the test data obtained, the transformers have been divided into three groups as follows:

Per cent power factor at 40 degrees centigrade: under 5.0, 274; 5.1 to 10.0, 136; over 10, 83.

This grouping is used as a follow-up in

Figure 3. Front view of type U tester used in reconditioning shop

Figure 4. Rear view of type U tester used in reconditioning shop

order to determine the trend of deterioration in the various units of a group from year to year.

Table IV shows the results obtained in drying out seven units in 1937. In all cases, the windings were removed from the tanks and dried out by the hot air method at 85 degrees centigrade. Subsequent tests to date on these transformers have shown that the "as left" readings have remained stabilized. The bushings were reconditioned in the shop and are included in both the "as found" and "as left" readings. Moisture was the contributing factor to the high pow in each case.

Instrument transformers and metering units rejected during the past five years are listed in table V. These units were reconditioned in the shop and again moisture was found to be the major cause for rejection.

D. MISCELLANEOUS

Several hundred defective supporting insulators have been removed from service either as a direct result of being found by test or by the inspection of equipment by the field test man.

Wood cross braces, *A* frames, lift rods, etc., have been reconditioned due to field investigation and rejection.

Power-factor test on oil samples is used as one of the criteria for recommending reconditioning.

Testing of lightning arrester units by power factor has resulted in the reconditioning of several hundred units due to

Table I A. Bushing Power-Factor Rating Schedule

Bushing Condition	Per Cent Power-Factor Limits for Various Type Bushings at 20 Degrees Centigrade				
	Kv	Condenser	Oil-Filled	Compound	Porcelain*
Satisfactory	15–37	0–3.0	0–3.5	0–3.5	0–3.5
Satisfactory	73–230	0–2.0	0–2.0	0–2.5	0–3.5
Follow-up	15–37	3.0–5.0	3.5–5.0	3.5–5.0	3.5–6.0
Follow-up	73–230	2.0–3.0	2.0–3.0	2.5–4.0	3.5–5.0
Replace	15–37	Over 5.0	Over 5.0	Over 5.0	Over 6.0
Replace	73–230	Over 3.0	Over 3.0	Over 4.0	Over 5.0

* Current and watts readings are of more value than power factor for this type of bushing.

Application of the above values may be somewhat arbitrary based on type of bushing construction, service requirements, and analysis experience. Approximately eight years of use has proved their reliability.

Table I B. Instrument Transformer Power-Factor Rating Schedule

	Per Cent Power-Factor Limits at 20 Degrees Centigrade				Per Cent Power-Factor Limits at 20 Degrees Centigrade		
Type P.T.	Satisfactory	Follow-Up	Replace	Type C.T.	Satisfactory	Follow-Up	Replace

E-115	5.0	5.0–7.0	Over 7.0	*K*-32	4.0	4.0–6.0	Over 6.0
E-16	3.5	3.5–5.0	Over 5.0	*K*-61	3.0	3.0–5.0	Over 5.0
E-116	3.5	3.5–5.0	Over 5.0	*K*-204	2.5	2.5–4.0	Over 4.0
P	3.5	3.5–5.0	Over 5.0	*OA*	4.0	4.0–6.0	Over 6.0
(34.5 kv) *VC*	3.5	3.5–5.0	Over 5.0	*O*-37	3.0	3.0–5.0	Over 5.0
(73 kv) *VC*	2.5	2.5–4.0	Over 4.0	*KE* (meter unit)	2.5	2.5–4.0	Over 4.0

broken castings, defective seals, corroded internal parts, etc.

V. Bushing Failures

Moisture was responsible for 69 per cent of the 48 bushing failures occurring between 1932 and 1940, as shown in figure 5. Entrance to the bushing was gained in most cases through defective gaskets or cement seals. In 1935, 12 of the 15 failures were caused by defective gaskets. This led to the program of replacing the top gaskets on nearly 1,000 bushings in place as previously reported.[1] Of the total failures (48), 27 per cent had never been tested and 6 per cent had been recommended for replacement previous to failure. The type *SI* compound-filled bushing was involved in 69 per cent of the failures with the condenser type accounting for 23 per cent. While it is not expected that failures will be eliminated entirely, it is definitely realized from the experience gained during the past eight years that many incipient failures were removed from the system.

Very few follow-up tests are made since the reconditioning shop was established. A bushing is now recommended for reconditioning if it does not pass the "satisfactory" rating. This eliminates the possibility of a failure between tests because the rate of deterioration is an unknown factor and also provides more time for productive effort on that equipment yet to be tested.

VI. Conclusions

From the experience gained and the data compiled in eight years of testing and reconditioning, the following conclusions may be logically presented:

1. The power-factor test has provided an adequate nondestructive method for determining insulation deterioration.
2. It is satisfactory in the results obtained and therefore justifies its continuation.
3. Due to the unknown factor "rate of deterioration" the period for testing of equipment at important locations should not exceed one year.
4. The major factor in insulation deterioration is moisture.
5. The rating schedules used for various types of equipment have proved satis-

Table II. Number of Bushings Rejected (1936 to 1940)

		Condenser	Oil-Filled	(SI) Compound	Porcelain	Total

MODERN theories of direct-stroke protection premise that the ground wires are so located as to intercept the stroke and provide perfect shielding. In spite of the fundamental importance of this question there still exists considerable doubt as to the correct position of the ground wires relative to the transmission conductors. Two avenues of approach are suggested for the attack of this question; first, the collection of statistical information regarding actual line performance, and second, the use of laboratory models. Line performance is, after all, the final criterion. However, it is difficult to isolate the shielding effect from other factors which may produce outage due to lightning. Studies with models eliminate this difficulty but always contain the element of doubt as to whether the laboratory conditions are sufficiently representative of actuality as to justify general conclusions. Perhaps the best course, that which is attempted in this paper, is to try both and co-ordinate the results so obtained.

Previous Investigations

Models have previously been used for investigating both the protective value of horizontal ground wires and vertical masts[1–9] for shielding transmission lines and other vulnerable objects such as substations, buildings, and oil storage tanks. In one of the earliest investigations with ground wires, Peek[3] states that "for a single wire, the ground is never hit nearer the projection of the wire than about four times its height above ground." Peek[4] further expands upon this point by stating that from model tests upon rods any object is protected if it lies between ground and within the surface generated by a segment of a circle whose center is the cloud height and is tangent to the ground and passes through the tip of the rod. This assumes that all the strokes occur to the object nearest to the origin of the stroke.[10] Upon this assumption a set of curves can be constructed as shown in figure 1 for guidance in the location of the ground wires with respect to the conductors. In this figure their relative location is specified in terms of the protective angle, the angle between the vertical and a line through the conductor and ground wire. The consideration of minimum sparkover distance just enunciated according to figure 1 indicates, for a cloud height of 1,000 feet and a ground wire height of 100 feet, a protective angle of about 65 degrees which is essentially constant over the practical range of conductor and ground-wire separations.

No data of any consequence such as tests on models of different scales have been presented in an attempt to show that model work is applicable to actual size systems although Peek in a reply to the discussion of his 1926 paper stated that "tests were made, however, over a wide range of scales with substantially the same results. In other words, for a given arrangement and ratio of rod and cloud height the results were independent of the scale." No data to substantiate this statement have been published.

Zalesski,[5] using impulse waves and continuous voltages, concluded that a positive cloud represented by a horizontal cylindrical electrode should be used for test work since it gave more pessimistic results. He determined the worst position of the electrode and with this position studied the necessary protective rod configuration to give complete protection to transmission lines and substations. Akopian[6] likewise limited his investigations mostly to vertical rods and agrees with Zalesski that positive impulse waves should be used in model tests. He departed from previous investigators by representing the cloud by means of a point electrode.

Schwaiger[7] in 1937 followed the philosophy that the conductors, if they are to be protected, must lie within the shaded areas shown in figure 2.

In 1939 Matthias and Burkhardtsmaier[8,9] presented results of investigations relating to shielding of transmission lines and other objects. They, however, premised that natural lightning of both polarities is adequately simulated by laboratory sparks of corresponding polarity. They used only one model scale which gave a reduction of 100:1. An argument was presented to justify the statement that for model work the protective value of a ground wire is not altered as the ratio of the cloud height to ground wire height is increased beyond a certain value. The effect of ground was represented by dry sand. They presented data which indicate a protective angle of the order of 23 degrees for a positive stroke and 31 degrees for a negative stroke.

Fortescue and Conwell[11] from practical considerations gained from experience on actual systems, advocated a protective angle of not more than 20 degrees.

Additional work appeared to be desirable to reconcile, if possible, the divergent views of different investigators. In the present investigation the authors have studied the mechanism of laboratory sparks and have shown that the propagation of leader streamers is quite closely simulated by positive waves of slow rates of rise. Arguments are presented to show that for practical purposes model investigations can be carried out with $1^1/_2$x40-microsecond positive impulses. Other points investigated are the effects of overvoltage, atmospheric conditions, scale of models, and height of cloud. After establishing the fundamentals of model investigations, considerations affecting construction practice such as the location of ground wires, topography of terrain, and soil resistivity, were studied. These questions were then co-ordinated with the results of actual system performance.

Mechanism of Natural Lightning

POLARITY OF STROKE

A knowledge of the characteristics of natural lightning is a prerequisite to an attempt to simulate its effect in the laboratory on a model scale. The present theories of charge formation are still controversial; suffice it for the present purpose to observe that it is concerned in some manner with the reactions between an upward movement of air, usually in the head of the storm, and a downward motion of water droplets. The droplets in the lower portion of the cloud are usually charged negatively and those in the upper portion, positively. This is borne out by the fact that 90 to 95 per cent of the strokes to transmission lines lower negative charge, by the measurement of electrical gradient at the ground in the vicinity of charged clouds[12] and by Simpson and Scrace's[13] measure-

ments of electrical gradients within storm clouds by means of free balloons. In addition, it appears that the charge density is nonhomogeneous and is distributed in zones or charge centers.

Rate of Charge Accumulation and Ground Gradients

The rate at which the charge accumulates is relatively slow as evidenced by the measurements of ground gradients by Wilson[12] and others. Figure 3 is a typical record obtained by Wilson which shows both the magnitude and manner of variation of this quantity. The division between the solid black and shaded areas indicates the magnitude of the gradient according to the scale on the left-hand side. Sudden discontinuities such as that at *A* and *B* represent the destruction of a portion of the gradient as the result of a lightning stroke. Immediately after the occurrence of a stroke the regenerative processes within the cloud begin to re-establish the field at the rate indicated by the rate of change of the gradient. It can be seen that in general the curve is exponential in character and requires a time of the order of several seconds before the charging process attains a substantially constant value. The prominence at 14 hours 12 minutes 30 seconds was produced by the measuring device to establish the zero line and is not a record of change in gradient due to a stroke. The fine weather gradient[13] at the surface of the earth is of the order of one volt per centimeter but during thunderstorms it may reach several hundred volts per centimeter.

Mechanism of Lightning Stroke

The knowledge regarding the mechanism of the actual discharge is due almost entirely to the work of Schonland[14] and his associates in South Africa. Approximately half of all lightning flashes are made up of a number of separate discharges or strokes which, for the region that can be photographed between cloud and earth, travel along the same path. The time interval between successive strokes may vary between 0.0005 to 0.5 second and the total duration may be a second, and in a few cases even longer. Infrequently the number constituting a single flash might be as high as 40.

Each stroke when resolved presents a rather complicated picture. During the process of charge formation or as a result of some local condition, such as vertical air convection currents, the electric field near the base of the cloud may rise to such an extent as to exceed the value which air can withstand. The discharge is then initiated at that point and propagates earthward at a velocity of the order of 1/20 of one per cent of that of light. The current associated with this so-called pilot streamer is small, of the order of a few hundred amperes and its luminosity is very low. As it proceeds, the pilot or leader streamer is accompanied by points of luminescence which move in steps or jumps, which give rise to the term "stepped leader". Each of these steps is about 50 yards in length with fairly regular pauses. This process usually involves a fresh direction of travel after each pause, and these changes in direction are responsible for the well-known zigzag nature of lightning. Branching of the leader streamer also occurs, the branching being outward toward the earth.

When one of these stepped streamers strikes the ground an intense streamer of very great luminosity is observed to travel from the ground to the cloud. The velocity of the "return" streamer is quite high, being of the order of 10 per cent of that of light. Its current is also very high, being of the order of 10,000 to 200,000 amperes, values which have come to be associated popularly with lightning.

From figure 4 it can be seen that as the leader streamer proceeds it lowers negative charge from the cloud and distributes it throughout the antenna-like system of streamers. This lowering of negative charge may consume a time of the order of 10,000 microseconds. As the stepped leader strikes the earth this same charge is lowered to earth at a rate dependent upon the rate of propagation of the return streamers, a process which requires a time of the order of 50 microseconds to reach the cloud. Thus the same charge which had been lowered and distributed over the streamer network in a time of the order of 10,000 microseconds is then discharged to ground in a time of the order of 50 microseconds. This accounts for the large difference between the pilot streamer and the return streamer currents.

Only a portion of the cloud charge is involved in this part of the mechanism. After the lapse of 50 or 100 microseconds the charge in the region between the cloud and ground is discharged and the stroke current at the ground decreases to a relatively small value. Thereafter the stroke current is determined largely by the rate at which leader streamers propagate into the cloud and tap more charge in that particular region.

After some time one of the leader streamers propagating into the interior may meet a similar leader emanating from another charge center. In this case the charge from the second charge center is discharged through the original lightning channel as shown in figure 4 and the same process is repeated except for the fact that the leader streamer is not branched and stepped. After the

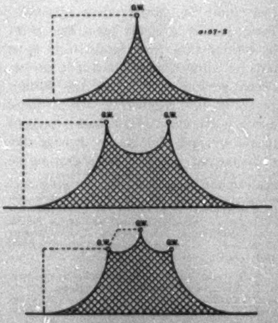

Figure 2. Protective zones of one or more ground wires[7]

charge from the second center has been dissipated, the same process may be repeated for the third and subsequent charge centers.

McEachron[16] has shown that in the discharge of lightning to a very tall building, the initial streamer usually proceeds upward from the building in the form of a stepped leader. This stepped leader then develops into what he terms a continuing stroke—a stroke of long duration and relatively small current. The subsequent strokes are similar to those which follow the first stroke of discharges that propagate from cloud to earth. From the published evidence and some small evidence obtained by the authors, the phenomenon of leader streamers from the earth appears to be characteristic, in the main, only of discharges to tall structures. Discharges to lower structures seem to lack ground streamers of any great length which rise to meet the pilot leader descending from the clouds. Schonland in a letter to the authors regarding his lightning investigations states that "it must be remembered that the country in which we work consists of rolling hills and valleys, so that the base of the discharge is often obscured, there must, however, be a large number of cases in which the full length of the discharge was recorded by the cameras and we have seen no evidence of any extensive leader discharge from ground. Such ground leaders as do occur are comparatively short, for otherwise we should have detected them."

Small streamers may and probably do exist which in the case of strokes to transmission structures rise from the tower or conductors. In general, however, the evidence available seems to point to the fact that in most cases the streamers, if any, are small.

The factors which control the path of the initial leader determine the point at which it strikes the line and therefore the shielding characteristics of an overhead ground wire. Upon completing the initial streamer the path is determined thereafter even to the extent of multiple strokes, all of which follow the same path blazed by the first discharge.

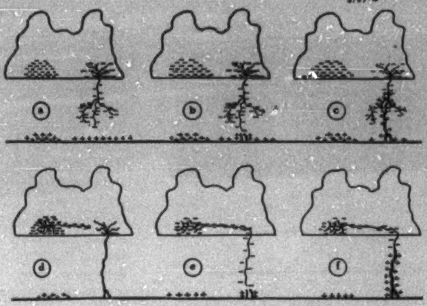

Figure 4. Propagation of natural lightning

Charge

According to Schonland,[15] the quantity of electricity conveyed by a lightning discharge varies between 2 and 100 coulombs with an average value of about 20, but McEachron[16] in his continuing strokes has measured a value as high as 164 coulombs.

Cloud Heights

A search of the literature reveals very little definite data regarding the height at which the stroke may be said to originate. Simpson and Scrace[13] from a limited number of cases obtained in England estimate charge centers as occurring as low as 1,500 feet and as high as 30,000 feet. Of course, the origin of the stroke may not coincide with the charge center but may lie between the charge center and the base. E. J. Minser, chief meteorologist of the Transcontinental and Western Air, may be quoted as authority that in his experience the altitude of the base of low-level thunderclouds frequently lies between 500 and 1,000 feet. He further states[17] that his studies show that the majority of lightning discharges were found to have occurred in the cumulus clouds of the shower type and that strokes to ground occur most frequently from clouds having the lower altitudes. Data in possession of the United States Weather Bureau indicate cumulonimbus clouds as having a mean ceiling of 5,500 feet with some of them as low as 600 to 700 feet. Thunderstorms for which the ceiling is practically zero are also reported at times. Cases for which the storm clouds actually envelop mountains rising from a plain are quite common.

In view of such data as the authors have been able to obtain it is believed that an altitude of 1,000 feet for the origin of the stroke is sufficiently representative and pessimistic for use in this paper.

Figure 3. Measurement by C. T. R. Wilson[13] of ground gradient during thunderstorms

Fundamentals of Model Tests

Allibone and Meek[18,19] have demonstrated certain similarities between the mechanism of natural lightning and that of long arcs obtained in the laboratory. It was considered advisable to extend the study of the mechanism of such laboratory arcs to determine the effects of their characteristics upon the protective performance of transmission line ground wires and diverters.

Description of Apparatus

A 3,000,000-volt 0.003-microfarad surge generator was used as a voltage source for the experiments. Various types of electrodes were used to represent the cloud, and for most of the work a smooth conducting plane represented the earth's surface upon which was placed the model to be tested.

In order to vary the wave shape of the voltage over a wide range, two different types of circuits were employed. The conventional surge-generator circuit with a resistance in parallel with the gap was used for waves with relatively steep fronts such as the $1^1/_2$x40 wave. As was done by previous investigators,[18] for

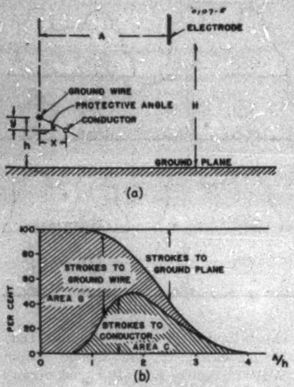

Figure 5. Symbols utilized with stroke distribution curves

waves of much smaller rates of rise this parallel resistance was removed and a high resistance placed in series with the gap. It was then necessary to use a capacity divider with the cathode-ray oscillograph for measuring the voltage. Since, as will be shown later, the shunt capacity of this circuit has a very pronounced effect upon the voltage wave shape its capacity had to be as small as possible. For this reason a short length of wire, about two feet long, was used as an antenna. The voltage of the ground plane was used as a reference and that of the electrode specified with respect to it.

A high-speed camera was constructed for the study of the visual characteristics of the laboratory stroke. It consists of a drum 13 inches in diameter which rotates at 3,600 rpm and is enclosed in a light-tight case. Thirty-five-millimeter film is placed on this drum and rotates past a stationary lens in a direction perpendicular to the direction of propagation of the stroke. It was found that satisfactory photographs could be obtained of the leader mechanism of arcs produced by voltages of slow rates of rise with an ordinary f/1.8 lens and Eastman Super XX film. Typical photographs of arcs made with this camera are shown in figure 6. The rotational speed of the film is such that time intervals as small as one microsecond can be measured. Since in all cases the time for the return stroke of the arc is much less than this, the image of the return stroke can be taken as the reference path for measuring the progress of the initial leaders. The camera will not photograph satisfactorily the leader mechanism of arcs produced with the standard $1^1/_2$x40 wave. This is due not only to the high speed of propagation of the leaders but also to the great luminosity of the return stroke. For this reason high-speed camera studies were restricted to the slower waves.

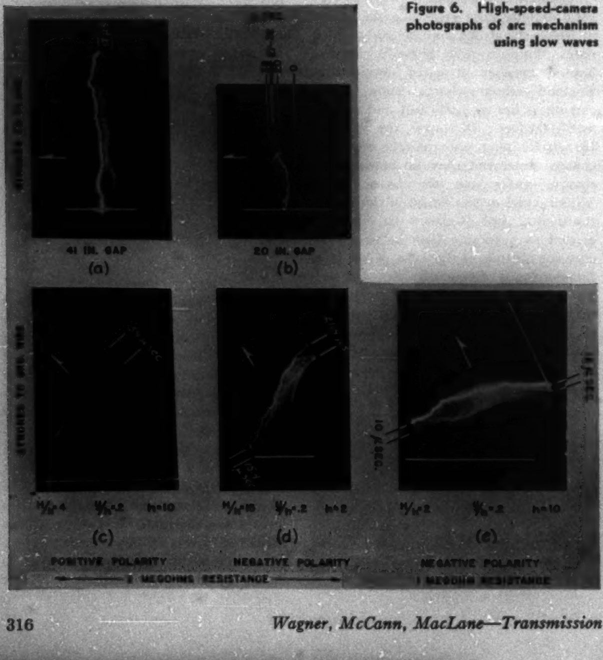

Figure 6. High-speed-camera photographs of arc mechanism using slow waves

Still photography was also employed for studying the visual characteristics of the arcs. Such pictures not only show the shape of the path of the arcs but also something of the character of the leader mechanism. For this reason they are particularly valuable for arcs which cannot be recorded by the rotating camera. In figure 8 are shown still photographs of strokes taken with the conductor and ground wire in place. They were taken in a direction parallel to the wires and thus, as nearly as possible, perpendicular to the arc path. Those showing more than one arc were taken by exposing the same film to a number of strokes taken in succession under the same conditions in order to show the variable character of the paths.

Distribution Curves

In this paper the lightning protection performance of a particular model configuration is based primarily upon distribution curves of the type shown in figure 5. The fundamental tests on ground-wire protection were made with one ground wire and one conductor as shown. The positions are specified by the following dimensions: h, the height of the ground wire above the ground plane; y, the vertical distance of the ground wire above the conductor; and x, its horizontal distance from the conductor. H specifies the vertical distance of the electrode representing the cloud source of the stroke above the plane (or cloud height) and A its horizontal distance from the ground wire, from the same side as that upon which the conductor is located. All dimensions are specified in inches. For a given configuration (value of h, x, y, and H) it is desired to determine the terminating point of strokes for various positions of the electrode corresponding to various values of A.

When the cloud electrode is directly above the ground wire all strokes terminate on the ground wire. As A is increased a position will be reached, if the conductor is not fully protected, for which the strokes divide between the ground wire and the conductor. Since this is a statistical phenomenon sufficient strokes should be observed, 50 is usually enough, so that a percentage division of the strokes between the ground wire and conductor can be determined. As A is further increased some of the strokes go to the plane and finally a position will be reached where all of the strokes go to the plane. The distribution curve of figure 5*b* is obtained in this manner. A/h is used as the abscissa in these curves instead of A so that models of different scale dimensions are directly comparable. Frequently cases occurred for which strokes terminated at more than one place as shown in figures 8*d* and 8*e*. Any strokes of this type which terminated on the conductor were counted as strokes to the conductor.

Because of the slow rate of charge formation in nature a better representation of the conditions of natural lightning is obtained if the minimum flashover voltage is used. Unless stated otherwise, all distribution curves were obtained by readjusting the voltage as A was varied to obtain the minimum spark-over value.

GAP AND PLANE

The slowest waves used were obtained with a series resistance of two megohms, which gave a wave rising to crest of the order of 50 microseconds. For this case it was not possible to obtain spark-over between point and plane for values of H greater than about 50 inches for positive polarity and 30 inches for negative polarity. However, when using the $1^1/_2$x40 wave spark-over could be obtained for spacings as high as 160 inches. For such a spacing a ground plane at least 20 feet square is necessary to eliminate edge effects. The difficulty of obtaining a smooth surface of such size was solved by the formation of a salt-water plane on the laboratory floor. Tests made with a dry metal plane, then with a metal plane covered with water, and lastly, with a water plane alone in which a network of wires was laid below the water surface to further improve its conductivity, showed no essential difference. The salt-water plane was employed for most of the tests.

MECHANISM OF SPARK

The first tests on arc mechanism consisted of determining the characteristics of arcs of both polarities for a point-to-plane gap. Some of the results of these tests confirm the previous work of Allibone and Meek and will be discussed here primarily from the standpoint of lightning protection. High-speed camera records obtained with a minimum flashover voltage and a very flow front using the surge generator circuit with a two-megohm series resistance, are shown in figures 6*a* and 6*b*. Examination of these two figures shows that in the case of negative polarity, leaders start from both the cloud and ground and meet about midway in the gap. However, with positive polarity there is only a positive downward leader. This characteristic difference has been pointed out by Allibone and Meek[18] and others to be due to the fact that a positive leader will propagate at a lower gradient than a negative leader. For this same reason the voltage required to cause spark-over of the positive point-to-plane gap is much lower than for the negative point-to-plane gap.

The negative downward leader for the case of the negative-polarity point electrode was found in most cases to be stepped in character as shown in figure 6*b*. The negative leader starts from the electrode at a very high velocity, too high to be measured with the high-speed camera, but dies out after progressing a short distance. Before the occurrence of the final streamer there may be several leaders of this incomplete character, each progressing further than the previous one. The final leader also moves at this relatively high speed until it has reached a point somewhat farther than the previous leader, then its velocity decreases rapidly and it moves over the final portion of its path at a fairly uniform speed, of the order of $^1/_{100}$th of a per cent of the speed of light. The positive leader which rises from the plane moves continuously at a fairly uniform velocity of the same low order of magnitude.

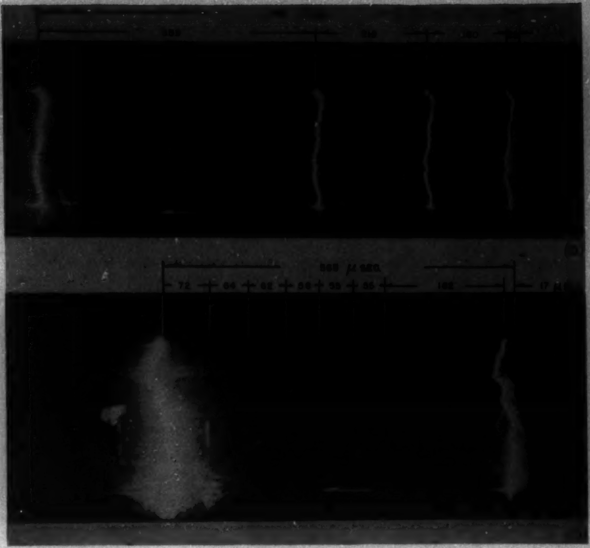

Figure 7. Laboratory multiple strokes

For the case of positive polarity the downward positive leader is sometimes also stepped and exhibits the same characteristics as the negative leader. Quite frequently, however, cases are found where it moves continuously, starting at a relatively slow velocity from the point electrode and increasing its velocity until it reaches a critical point in the gap, then proceeding for the rest of its distance at a uniform velocity of the order of magnitude of $^1/_{100}$th of a per cent of the speed of light.

Similar tests made with the ground wire and conductor in place are shown in figures 6*c* and 6*d*. In this case it is seen that for negative polarity the upward positive leader is the more predominant one, there being only a short negative downward leader. For positive polarity the reverse is the case, there is only a very short upward leader. The character of the positive leaders for

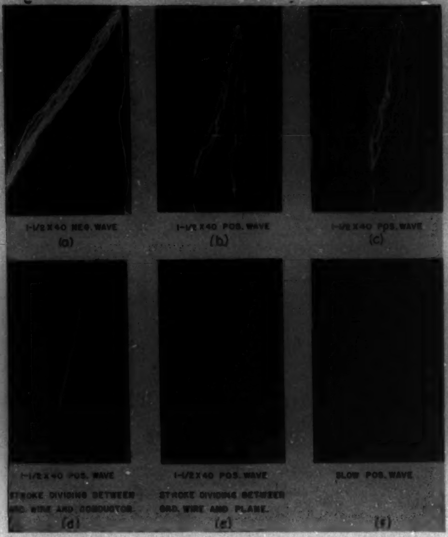

Figure 8. Still photographs showing character of arc paths

the two polarities are similar to those for the point-to-plane gap.

The relative development of the two initial leaders is thought to play a dominant part in determining the distribution curves and it is felt that this is one of the most important characteristics which must be correctly simulated in the model. As will be recalled, the discharge of natural lightning, which is usually negative, is accompanied by very little streamer formation from the earth. Peculiarly, this is more closely represented in the laboratory by a positive discharge which likewise has relatively small leaders emanating from the ground plane. Negative strokes in the laboratory, on the other hand, have quite large streamers from the plane. The difference between the character of the negative stroke in the laboratory and in natural lightning in this regard is probably due to the relative difference in the field gradients at the ground in the two cases. It is thought that these gradients are much higher in the model due to the fact that it is not possible to get breakdown of a point-to-plane gap without a certain amount of corona streamer formation from the point electrode. This increases the effective size of the electrode and thus the field gradient at the ground for a given voltage. Further, this tends to decrease the field at the upper electrode and increase the voltage necessary to cause the leaders to progress downward. Due to this fact it is thought that the ratio of the cloud potentials in the case of natural lightning to the model potentials is considerably less than the ratio of their dimensions. These differences may be increased further by the lower breakdown strength of air at the high altitudes at which the stroke originates in natural lightning as compared to that at the earth.

One factor which is influenced greatly by the character of the wave shape is the duration of the luminosity of the leaders and the current which flows from the electrode into the leader. The capacity of the point-to-plane gap is relatively small so that if no additional capacity is in parallel with it the regulation of the voltage at the gap is very poor when a large series resistance is used. At the instant the leader starts from the electrode enough current is drawn through the series resistance to cause the voltage to drop. Under such conditions of regulation the current flows into the leader only a very short time after its start from the electrode. The leader propagates at a relatively low velocity and its luminosity dies out rapidly behind the leader tip. Thus the leader photographs on the rotating camera film as a narrow line. This is shown in figure 6*d*. In the case of natural lightning it is thought probable that a considerable voltage drop may exist in the lightning channel during the propagation of the downward leader. This is caused by the recombination of free charges behind the leader tip. For the laboratory arcs this condition is greatest for the above type of discharge due not only to the fact that a negligible amount of current flows into the leader to re-establish its conductivity, but also due to the drop in the series resistor.

As the regulation of the voltage is improved by the addition of a parallel capacitor the current flowing into the leader and the luminosity of the leader persists for a longer time. The record shown in figure 6*a* was taken with a sphere gap in parallel with the point-to-plane gap. By varying the spacing of the sphere gap

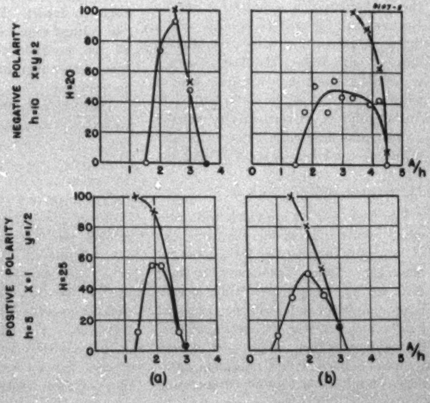

Figure 9. Effect of wave shape

(*a*)—1½x40

(*b*)—Slow rate of rise

it served as a variable capacitor. The increased duration of the leader luminosity is evidenced by the wide band of lower luminosity to the right of the return stroke. This record also shows a greater amount of branching of the leader than in the case shown in figure 6*c*.

By the addition of such capacitance it is also possible to produce multi strokes having many of the characteristics of those occurring in natural lightning. Allibone and Meek produced such strokes in this way. In figure 7*a* is shown a series of repetitive strokes produced in this manner. By varying the magnitude and wave shape of the applied voltage and the parallel capacity the number of repetitive strokes, the time between them, and the magnitude of the stroke current can be varied over a wide range. By this method it is possible to study the recovery characteristics of air. In figure 7*b* is shown a case in which there are only two strokes 565 microseconds apart. This record is of interest because it shows the presence of a stepped leader for the second stroke.

As stated previously, the process of charge generation in actual clouds is relatively slow. One would expect that the laboratory representation of this condition would be most closely simulated by a continuous voltage. This condition is difficult of attainment but can be approximated by the use of waves of very slow rates of rise. As will be shown subsequently, this is not a very important factor. As the time to crest of the wave is decreased or the crest magnitude of the voltage is increased the speed of propagation of the leader increases. The velocity of positive leaders of continuous character increases uniformly. For leaders of stepped character the number of stepped leaders decreases rapidly. The effective velocity of the negative leader increases somewhat faster than that for the positive. High-speed camera records, obtained when the rate of rise of voltage is gradually increased by decreasing the series resistance, show this effect. Figure 6*e* is a record of a negative stroke to the ground wire when a series resistance of one megohm is used. This shows a negative leader bridging about one-third of the gap as compared with the much shorter leader of figure 6*d*.

The effect of waves of very steep fronts such as those of standard $1^{1}/_{2}$x40 waves, can be studied by still photographs. The direction of branching of leaders of both polarities is always in the direction of its propagation. By this means it is known that a particular leader progressed at least as far as the last branching point. As the leaders approach each other they branch out, and frequently several meet simultaneously, the return strokes occurring along all of them. This forms several parallel paths over a short distance of the arc at the junction point of the two leaders and provides another method for determining the meeting point of the leaders. Both of these characteristics can be seen on the photographs of figure 8.

The examination of many such still pictures shows that for the $1^{1}/_{2}$x40 wave the essential characteristics of the point-to-plane gap alone and with the ground wire and conductor in place are the same as with the slower waves. However, the relative development of the negative leader, although rather variable, is usually somewhat greater. This is most noticeable in the case of positive polarity strokes for which the negative upward leader is found to have maximum lengths as high as one-sixth the gap spacing for point-to-plane gaps and one-fifth for

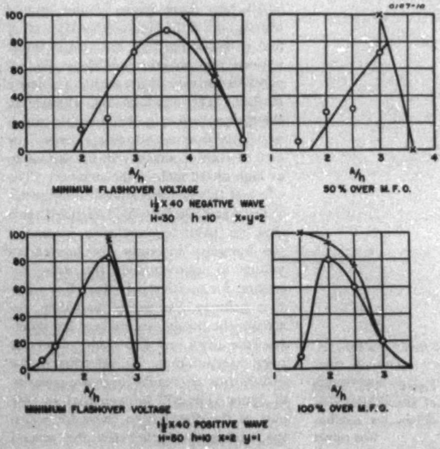

Figure 10. Effect of overvoltage on distribution curves

point-to-wire gaps for a ratio of *H/h* of five to one. The corona streamer formation at the cloud electrode was found to be considerably greater for the $1^1/_2$x40 wave than for the very slow one. This additional effect tends to increase the field gradient at the plane and thus the relative development of upward leaders.

Wave Shape and Distribution Curves

Results of studies to determine the effect of the character of the applied voltage upon the distribution curves for both positive and negative strokes are shown in figures 9 and 10. Figure 9 shows the effect of wave shape and figure 10 that of overvoltage. From these results it is seen that the nature of the stroke voltage influences greatly the curves for negative polarity strokes and has little effect on those for positive strokes. The greatest discrepancy caused by varying voltage conditions for negative strokes is in the variation of the position of the portion of the distribution curve formed by the division of strokes between the wires and the ground plane. The slower the rate of rise of voltage the larger the value of *A/h* before strokes start to go to the plane. Thus a greater proportion of strokes will go to both the ground wire and the conductor and the conductor is less protected for this type of wave.

The effect of voltage upon the character of the distribution curves can be explained by the nature of their leader mechanism. The spark-over characteristics of the point-to-plane gap and the point-to-wire gap are more nearly equal for positive-polarity sparks than for negative ones. This is due to the fact that the positive-polarity spark is initiated by a positive downward leader traveling practically all the way across the gap for both gap configurations. The time lag and the voltage required for spark-over are more nearly the same for positive polarity and little affected by the character of the voltage. The somewhat larger upward leader in the case of the $1^1/_2$x40 wave has no appreciable effect on the distribution curves. However, for negative-polarity strokes the point-to-wire gap is initiated by an upward positive leader which progresses most of the gap length, while for a point-to-plane gap the leaders progress simultaneously from both electrodes toward the center of the gap. For this reason the time lag of the point-to-plane gap is less than that for the point-to-wire gap. However, the point-to-plane gap requires a higher voltage for spark-over for the same spacing. Thus voltages of slower rates of rise will break down the point-to-wire gap more readily.

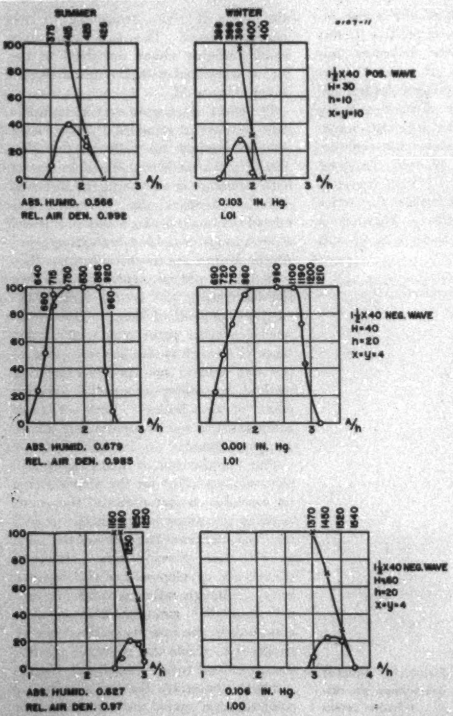

Figure 11. Effect of atmospheric conditions on distribution curves

Weather Conditions

All tests were made in the natural atmosphere of the high-voltage laboratory and it was found that data taken under various atmospheric conditions did not check in the case of the negative-polarity strokes. The predominant change in the atmosphere is in the humidity which may vary from an absolute value as low as 0.01 inch of mercury in the winter to as high as 0.6 inch in the summer. The effect of this factor is shown in figure 11.

Data published by Y. Ishiguro[20] show that for point-to-plane gaps increasing the humidity increases the breakdown voltage in approximately the same proportion for positive polarity. For negative polarity, increasing humidity decreases the breakdown voltage for point-to-plane gaps and has little effect for point-to-point gaps. In referring to the distribution curves for negative polarity of figure 11 it will be seen that in that part of the distribution curve for which the strokes divide between the ground

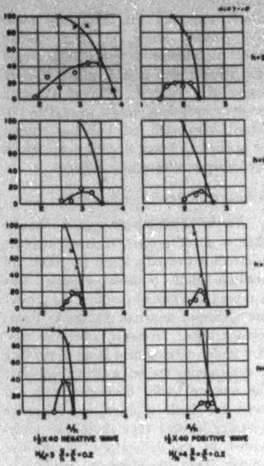

Figure 12. Effect of changing scale

wire and conductor the breakdown voltage is not influenced to any considerable extent by humidity but where the strokes divide between the wires and plane increasing humidity decreases the breakdown voltage. Applying Ishiguro's data indicates that there should be no substantial change when the distribution occurs between wires but where the distribution occurs between wires and plane a greater proportion of the strokes should go to the plane at higher humidity. This has the effect of moving the distribution curve to the left in this region. In the case of positive polarity the breakdown voltage of both point-to-wire and point-to-plane gaps are affected only slightly and therefore one would expect little effect upon the distribution curves as is borne out by the results of figure 11 and a considerable amount of other unpresented data.

GEOMETRIC SIMILITUDE

Tests were made to determine the effect of geometric similitude. In figure 12 is shown some of the data in which the scale dimensions were varied over a range of eight to one. The results of these tests indicate that the range of scales considered has no very great effect upon the distribution curves for positive strokes. The very small effect that may be present is in a direction to make the protective value less for small scales, which would produce pessimistic results in model work. There is, however, a very definite effect for negative strokes. As the scale is increased, and thus the spacing between the cloud electrode and ground, the range of A/h for which shots go to the wires decreases and approaches the results obtained with positive strokes.

FACTORS AFFECTING ARC PATH

Examination of the still pictures of figure 8 show how variable the path of the arc is even though conditions are maintained as nearly constant as possible. As the leader tip progresses it is apparently very unstable and easily affected by its own irregularities. For this reason it follows a tortuous path. The paths of the negative polarity strokes are much straighter and more closely grouped than those of positive strokes, while the paths of the arcs of slow voltage waves are more spread out and more irregular than those of the $1^1/_2$x40 waves.

In considering these factors it is convenient to segregate the field at the tip of the leader into two parts: that produced by charges remote from the tip including the effect of the leader from the opposite electrode; which will be called the directive field; and that produced by the ionization phenomena taking place in the region of the leader tip. The irregularities at the tip cause one arc to have a totally different path from another and possibly a different terminating point; thus the division of strokes in distribution curves. The first component of the field has, however, a very definite directive effect in influencing the ionization process at the leader tip and an appreciable upward leader influences the downward one.

The greater irregularity of arcs produced by slow waves is probably due to the fact that since the breakdown voltage is less the directive field is weaker and has less directive effect. It thus approaches more closely the case of natural lightning. By taking a large number of shots in obtaining the distribution curves a statistical average is obtained of the effect of the factors which influence the path of the arc. The fact that wave shape has no effect upon the distribution curves for positive polarity indicates that on the average the actual magnitude of the directive field is not important. It is merely its relative value throughout the region in which the arc might progress that determines the average result.

The greater upward leaders in the tests with the $1^1/_2$x40 waves over those in the tests with slow waves had no effect upon the distribution curves. Arguing from these results, the extremely small upward leaders that may occur with natural lightning should be insignificant in determining the terminating point of the stroke.

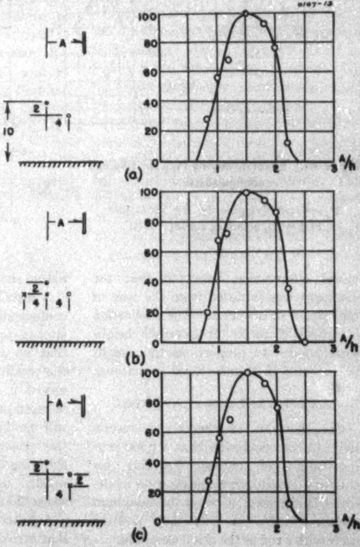

Figure 13. Effect of the presence of other conductors on the protection of the most exposed conductor

$1^1/_2$x40 positive wave, $H/h=3$, $y/h=2$

So far leader development and distribution curves have been considered for a rod electrode only. It was felt that perhaps the shape of the electrode might have a certain directive effect upon the leader in its vicinity and thus influence the distribution curves. To test this point a special electrode was made by soldering a small wire one-half inch long to a ten-inch sphere. With the wire directed downward from a height of 30 inches a distribution curve was obtained for $h=10$, $x=4$, and $y=2$. This electrode gave the same distribution curve as a rod electrode and visual observation indicated that the discharge was initiated from the wire of the sphere in all cases. The proportion of sphere diameter to electrode height corresponded to proportions that might be expected in thundercloud formations.

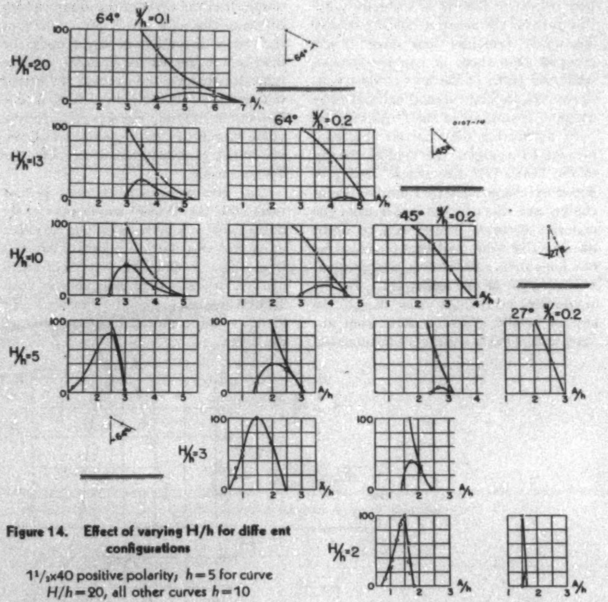

Figure 14. Effect of varying H/h for different configurations

$1^{1}/_{2}$x40 positive polarity; $h=5$ for curve $H/h=20$, all other curves $h=10$

Final Choice of Laboratory Model

Consideration of the above results leads to the conclusion that a good representation of natural lightning for studying ground wire shielding on model scales is obtained by using the minimum flashover value of a $1^{1}/_{2}$x40 positive wave with a rod as the cloud electrode.

It must be remembered, however, that any results which can be deduced with models can only be of a statistical nature. The distribution of charge within a thundercloud is likely to be unsymmetrical about the point of origin of the discharge and will influence to some extent the shielding value of the ground wires. In open, level country this dissymmetry should, however, be eliminated by the statistical averaging of a large number of strokes. Where the prevailing storms in a locality originate from the same direction this may be true but, in general, any effect of this nature should be very small.

A distribution curve obtained for any configuration which shows no area for strokes to a conductor does not mean that no strokes will ever terminate on the conductor. If enough shots are observed it will be found that eventually in most practical configurations a stroke will finally strike the conductor. For this reason isolated records of natural lightning which show strokes terminating within certain regions of protective space should not be overemphasized.

Another important consideration is that strokes to very tall buildings more closely approach the laboratory negative polarity stroke in their relative leader development. Since it is found that strokes with a predominate upward leader give entirely different shielding results conclusions drawn from data obtained from such tall buildings cannot be applied to lower structures for which the leader development is different.

Attractive Effect of Polarity

Allibone[19] from laboratory tests showed that a small projection from a plane electrode attracted a larger proportion of negative than positive strokes. This was used as a basis to explain the greater prevalence of negative strokes to transmission lines. However, since the relative leader development is all controlling in determining the point struck and since the relative leader development is the same for both positive and negative lightning strokes they should be represented in the laboratory by positive waves. This consideration would appear to throw doubt upon this explanation for the prevalence of negative strokes to transmission lines.

Results of Model Tests

Wire Size

Correct proportioning of the model wires to those in actual practice resulted in destruction of the wire for each shot. Recourse was therefore had to larger conductors. Distribution curves made with wires of diameters varying from 0.008 inch to 0.09 inch showed that wire size has negligible effect for positive polarity. Tests made with negative polarity however as may be expected are not so consistent.

Grounding of Conductors

The speed of leader development is so slow that it is thought that both the ground wire and conductor, except for the dynamic voltage, remain at essentially ground potential during the development of the leaders. However, to verify this point the effect of having both the ground wire and conductor grounded was compared with the case for which the ground wire was grounded but the conductor connected to ground at each end through 500-ohm resistors to represent the surge impedance of the line. Little difference was found for these two cases. Other tests in which the conductor was insulated gave somewhat better protection. The most pessimistic results are obtained by grounding the conductor, a condition under which all subsequent tests were made.

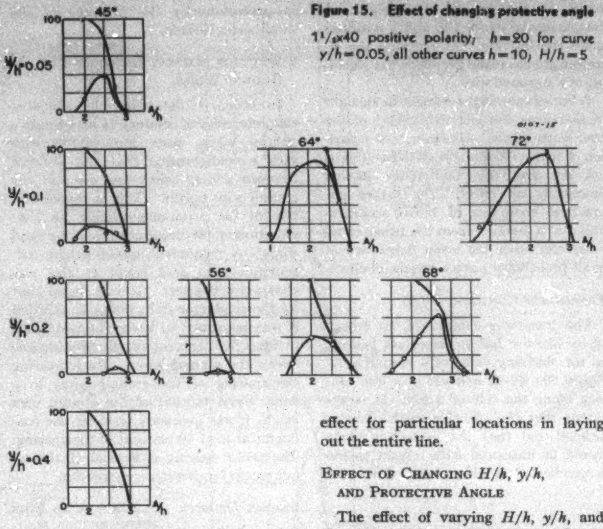

Figure 15. Effect of changing protective angle

$1\frac{1}{2}$x40 positive polarity; $h=20$ for curve $y/h=0.05$, all other curves $h=10$; $H/h=5$

Presence of Other Conductors

Actual transmission-line construction involves more complicated conductor configurations than the simple ground wire and single-conductor arrangement so far discussed. To determine the effect of the presence of other conductors upon the general problem of shielding, tests were made upon several arrangements of ground wire and conductor. Figure 13 shows a portion of the results of these tests in the form of distribution curves. It was found that the added conductors of *b* and *c* which are indicated by x's were not stricken as the electrode was moved to the right of the ground wire. In addition, the distribution curves are not influenced by the presence of the added conductors. Additional ground wires likewise had little effect. The following data are, therefore, confined to the single-ground-wire and single-conductor configurations.

Towers

The point from which insulators are supported on steel suspension towers is directly above the conductor and naturally tends to protect it. Tests show, however, that the extent to which this is effective is unimportant in level terrain. In mountainous conditions particular towers supporting spans having large sags might prove to be advantageous from this viewpoint. It would be unwise, however, to take advantage of this effect for particular locations in laying out the entire line.

Effect of Changing H/h, y/h, and Protective Angle

The effect of varying H/h, y/h, and the protective angle are shown by the distribution curves of figures 14 and 15. In figure 5 areas *G* and *C* are proportional to the total strokes to the ground wire and total strokes to the conductor, respectively. The ratio area *C*/(area *C*+ area *G*) then represents the proportion of the total strokes to the structure which strike the conductor. Data of the character shown in figures 14 and 15 supplied information from which the curves shown in figures 16, 17, and 18 were plotted. Figure 16 shows that the strokes to conductor decrease continuously as H/h is increased. This result is in direct variance with that obtained by Matthias[5,6] who concluded that above a value of H/h of 7 the proportion of strokes which strike the conductor is constant. Figure 17 is interesting in showing the general effect of changing y/h while keeping the protective angle and H/h constant. Figure 18 shows how the strokes to conductor vary as the protective angle is altered for different values of y/h.

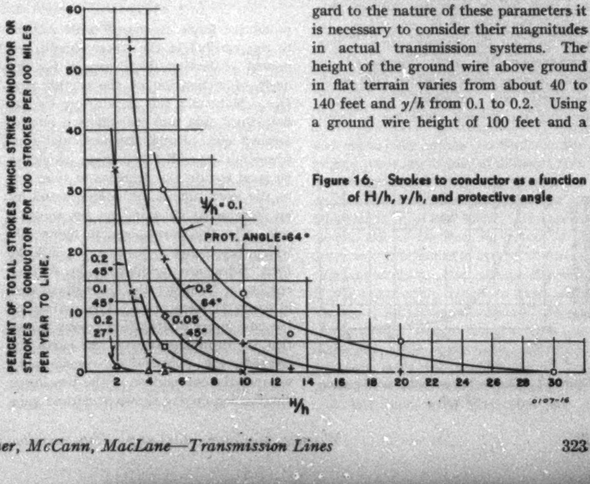

Figure 16. Strokes to conductor as a function of H/h, y/h, and protective angle

The curves of figure 1 were plotted on the theory that the stroke strikes the nearest object, that is, either all the strokes terminate on the ground wire, all on the conductor, or all on the plane. For H/h equal to 5 the protective angle is 55 degrees and is essentially independent of y/h. Figure 18 emphasizes that the desired configuration is dependent to a very great extent upon the degree of shielding to be expected. Thus for 99 per cent shielding the protective angle varies between 46 degrees and 60 degrees as y/h varies between 0.05 and 0.2 and if y/h is 0.1 the protective angle varies between 51 degrees and 72 degrees as the shielding varies between 99 per cent and 95 per cent.

The safe location of a conductor has frequently been described as any position within a volume enclosed by two plane surfaces intersecting the ground wire and making an angle of 45 degrees with the vertical. The curves of figures 17 and 18 show that these surfaces should not be plane but curved concave upward in a manner similar to that shown in figure 2 by Schwaiger. However, the curves by Schwaiger result in protective angles which are entirely too small.

In order to orient one's self with regard to the nature of these parameters it is necessary to consider their magnitudes in actual transmission systems. The height of the ground wire above ground in flat terrain varies from about 40 to 140 feet and y/h from 0.1 to 0.2. Using a ground wire height of 100 feet and a cloud height of 1,000 feet, gives a value of H/h equal to 10. Examination of figure 16 indicates that for these conditions and y/h equal to 0.2, and a protective angle of 64 degrees, 5 per cent of the strokes strike the conductor. It must be understood, however, that these conditions are not met in practice except in flat country with very low soil resistivity. In rough, rugged, and hilly country advantage is usually made of locating towers on prominences so that the effective height of the ground wire above ground is considerably in excess of that at the tower. This fact prompts the use of a smaller value of H/h and y/h than just mentioned, both of which decrease the protection afforded by the ground wire. For example, if h is doubled the corresponding values of H/h and y/h would then become 5.0 and 0.1, respectively, and from figure 16 it can be seen that 30 per cent of the strokes would strike the conductor.

Soil Resistivity and Counterpoise

Soil resistivity might likewise affect the appropriate value of h to use. The propagation of the initial leader of natural lightning is so slow that for ordinary soil conductivity the surface of the earth is probably maintained at essentially the same potential. For dry, sandy, or rocky soil this consideration does not apply and the equivalent depth of earth plane should be lower than the actual surface of the earth. Matthias[9] in his model work took as a representative case a layer of dry sand of approximately the same depth as that of the ground-wire height. While this may be typical in so far as resistivity of the soil and geometric similitude is concerned it does not follow that the voltage gradients in the earth are in proportion. In order to show the general nature of this phenomenon the tests illustrated in figure 19 were made in which high earth resistivity was simulated by simply lowering the ground plane by a depth equal to the ground-wire height. A comparison of figure 19a and b indicates quite conclusively that lowering the effective ground plane decreases the shielding of the ground wire.

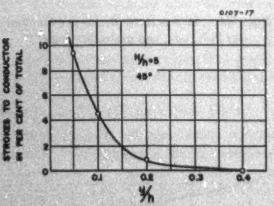

Figure 17. Strokes to conductor as a function of y/h

A buried counterpoise might be thought of as raising the effective height of the true water plane. However, a comparison of figure 19b and c shows that this is not the case, the counterpoise having practically no effect. The rather impractical condition of buried counterpoises at a distance from the tower equal to several times the tower height would in all probability have a beneficial effect.

Transverse Contour

The transverse contour of the topography likewise has an important bearing on the shielding value of a ground wire. Figure 20a shows a tower of a line running along the side of a hill. It is apparent that the effective earth plane is inclined and that the protective angle should be measured with respect to the perpendicular to this plane. Thus the protective angle measured with respect to the vertical of the tower should, for perfect protection, be increased by the angle of inclination of the earth's surface. Naturally this is additive on the downward side and substractive on the upward side. But if the particular configuration provided adequate shielding on level terrain the decrease in shielding on the lower side is not counteracted by an increase in shielding on the upward side. For the case shown in figure 20b which represents a tower on a hillock, both sides are additive. To further emphasize this fact the tests illustrated in figure 21 were made. Comparison of the two upper distribution curves shows that the dropping away of the earth decreased the protection considerably whereas the comparison of the two lower distribution curves shows a marked gain in protection by the presence of the neighboring hillside.

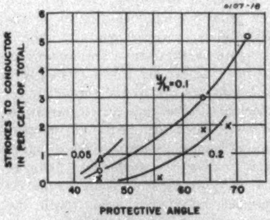

Figure 18. Strokes to conductor as a function of protective angle for H/h = 5

Conductor Midway Between Two Ground Wires

In order to determine the shielding characteristics of conductors between two ground wires, tests were made with such a configuration that the distance between ground wires was one-half the ground wire height. This is representative of the maximum spacing for construction employing conventional ground wires. A pessimistic cloud height corresponding to H/h equal to five was chosen for the test. It was found that for the conductor to be perfectly shielded it was necessary to lower the conductor at least 15 per cent of the spacing between the ground wires. By increasing the spacing of the ground wires to a value equal to that of the ground wire height it was necessary to lower the conductor at least 10 per cent of the spacing. The latter spacing is typical of the requirement for diverter construction.

Stroke Density and Strokes to Line

In an effort to apply a quantitative measure to the effectiveness of ground-wire protection a knowledge of the number of strokes to the line, S, per hundred miles per year is required. As shown in the appendix this quantity in terms of the stroke density, D, in number per square mile per year, is equal to $Dh/26.4$ (area G + area C). From a knowledge of the distribution curves which were obtained for a wide variation of h, H, x, and y, the quantity S/Dh may be plotted as shown in figure 22a. The strokes S are thus proportional to D and are a function of H and h. In figure 22b these data are replotted with S/D as the ordinate and H as the abscissa for h equal to 50, 75, and 100 feet. It is interesting to observe that for a given stroke density the strokes to the line increase with the height.

Tests with two ground wires separated varying distances up to one-half the ground-wire height showed little difference in the total area representing strokes to the structure. Thus there should be little difference between the total strokes to a line with a single or double ground wire or between a single- or double-circuit line. In what follows strokes or outages will be based on a line rather than a circuit basis.

published data are available and, in addition, a number of utilities have made available to the authors certain unpublished data.

STROKES TO LINE

E. Hansson and S. K. Waldorf, from data obtained with magnetic links between 1935 and 1938 upon 703 mile-years of operation of lines of the Pennsylvania Water and Power Company, indicate an average of 116 strokes per 100 miles per year. Bell[21] from data accumulated between 1926 and 1933 on the portion of the Wallenpaupack-Siegfried line (without ground wires), obtained a value of 82.8 flashed towers per 100 miles per year. This figure is probably lower than the actual number of strokes to the line as some of the strokes may not have left their markings. In the same period data for the same line indicated an average of 25 tripouts per 100 miles per year. A comparison between these figures shows that the frequency of lightning strokes should be considerably in excess, something of the order of three times, the number of outages. Table I is a compilation of outage data for a number of high-voltage lines without ground wires. The weighted average of these lines lies between 30 and 35. Applying the factor three to these values results in an estimated value of 100 strokes per 100 miles per year. It must, of course, be remembered that this value is very much of an approximation and will vary with location and other factors. The ordinate of figure 16 which expresses the per cent of strokes which strike the protected conductor can also express numerically the number of strokes to the conductor on a basis of 100 strokes to line per 100 miles per year.

STROKES TO CONDUCTOR AND OUTAGE DATA

The next step is to verify to what extent the data of figure 16 represent the performance of actual system operation. Before this is attempted it is well to point out some of the difficulties encountered in this task. It will be observed first that the performance to be expected of any configuration will depend to an enormous extent upon the particular assumption of cloud height or H/h. As pointed out previously, very little data are available upon this point. Cloud heights may and do vary with geographical location and local topography. Along with the variation of storm numbers per year at different locations there also exists variations in range of these heights. Two similar lines at different locations might therefore have entirely different performance records. The variation of shielding with H/h as shown in figure 16 therefore anticipates that difficulties might be present in the comparison of system performance.

In forming an opinion of what is adequate protection the criterion will be adopted that the strokes to conductor should be less than one per 100 miles per year. For a value of H/h equal to 10 the curves of figure 16 indicate that a protective angle of 60 degrees is adequate for a value of y/h equal to 0.2 and 50 degrees for y/h equal to 0.1.

Further obstacles are encountered when an attempt is made to verify the extent to which these data represent the performance of actual systems. It is difficult to isolate the effect of shielding alone. Even for systems of very low tower-footing resistance the question still arises as to whether flashovers might not be due to currents of high rates of rise for which the tower surge impedance and strokes to midspan become important. Thunderstorms are usually accompanied by wind and since the phase conductors and ground wires are usually of different type and sagged differently the protective angle may be considerably greater at midspan than at the tower. Of course, on one side of the line the increment of angle would be additive and on the other side subtractive. The outage function is not linear with respect to angle and, therefore, the increased angle will cause a much greater outage increase than the decreased angle a decrease. However, in some cases the smaller sag of the ground wire may completely annul this condition and even give the line a

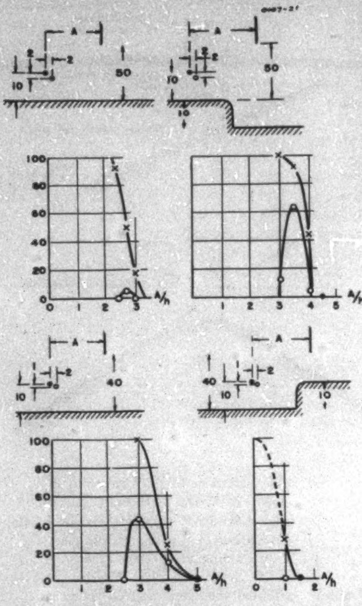

Figure 21 (left). Effect of uneven ground plane

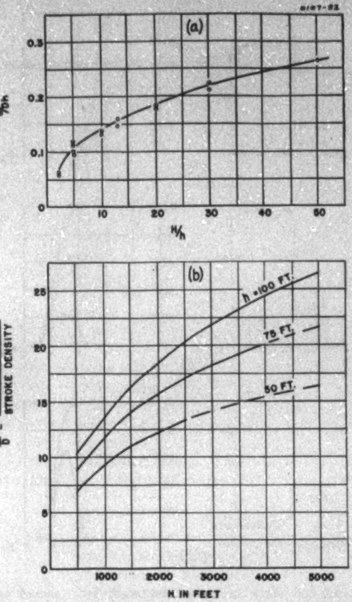
$1\frac{1}{2}\times40$ positive polarity

Figure 22 (right). Strokes to transmission line as influenced by cloud and ground-wire height



smaller protective angle at midspan.

Hansson and Waldorf have supplied the authors with the data tabulated in table II. It will be observed that the Safe Harbor lines to Westport, Riverside, and Perryville, all have protective angles well within the values set by the curves as being adequate and the operating experience verifies this result. The Holtwood-Coatesville line, being nearer the limits set above, offers a better opportunity to check the laboratory results. Inspection of the curves in figure 16 for H/h equal to 10 and y/h equal to 0.1 shows that the per cent of strokes which strike the conductor is of the correct order of magnitude, the curves being somewhat pessimistic.

The Fort Wayne-Marion-Muncie line of the American Gas and Electric Corporation is interesting in that it has very low tower-footing resistances, the average being about 2.5 ohms. The protective angle is 50 degrees and y/h is 0.11. Data obtained from I. W. Gross giving operating results over a five-year period, representing 400 mile-years of operation, shows 23 flashovers which is equivalent to 5.7 per 100 miles of line per year. As stated previously, the curves of figure 16 for H/h equal to 10, y/h equal to 0.1, and protective angle of 50 degrees give one stroke per 100 miles per year, a value which is somewhat low with respect to the actual performance. It is probable that the change in angular position occasioned by wind conditions is an important factor in this case since the line is so close to the critical angle.

A number of utilities have maintained rather accurate records of the resistance of each individual tower and the particular ones upon which flashovers occurred. By dividing the towers into classes according to their resistances and sorting the flashovers into the same classes it is possible, by weighting the flashovers according to the number of towers in the class, to plot a curve of flashovers as a function of tower-footing resistances. This has been done for data relating to flashovers and outages for several companies. The intercept with the ordinate for resistance equal to zero should represent the effect of lack of shielding, tower impedance drop, and possibly the effect of ground-wire impedance for strokes to midspan. Figure 23 represents data of this type obtained for a 132-kv system in flat country of low soil resistivity. Data of this nature are of necessity somewhat random in character and it is difficult to determine the curve to be drawn through the plotted points. The significant fact is that the ordinate intercept for resistance zero is zero or very small. This would indicate not only satisfactory shielding but also that the effect of tower surge impedance is negligible. Published data[22] for the Victoria Falls-Transvaal Power Company, plotted in figure 24, shows a similar result. This line also transverses relatively flat country. The results of these two systems check the data from the model work.

Similar data supplied by I. W. Gross applies to the system of the American Gas and Electric Corporation and is plotted in figure 25. Accepting the result of the two previous curves that the effect of tower surge impedance is not of any great importance, the y-intercept of 12 flashovers per 100 miles per year must be attributed to poor shielding. This number contrasts with about one per 100 miles per year for y/h equal to 0.1 and a protective angle of 45 degrees as dictated by figure 16. For the same time for which these curves were obtained the total flashovers of 521 corresponded to 371 tripouts. Applying this same ratio to those due to lack of shielding provides a value equal to nine tripouts per 100 miles per year. A large portion of the lines involved in this group traversed mountainous country in which the effect

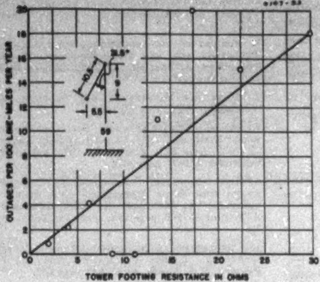


Figure 23. Lightning outage record of lines of 132-kv system in flat country

1,470 mile-years of single and double circuit

$x/h = 0.093$, $y/h = 0.152$, protective angle = 31.5 degrees

of transverse slope, the decrease of y/h across valleys and canyons, and the lowering of the equivalent ground plane might be of considerable importance. It is also possible that because of the mountainous terrain, the cloud heights, and thus H/h, are lower. In general, the height of the ground wires on these lines is larger than for the lines previously considered, so that for a given cloud height H/h is smaller which likewise tends to decrease the shielding. Perhaps in view of these factors the agreement is not as bad as might first appear. If the disagreement is to be attributed to these causes, then it follows that the nominal protective angle and y/h at the towers must be corrected in some manner to take these factors into consideration.

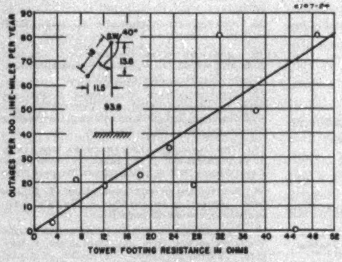

Figure 24. Lightning outage record of lines of Victoria Falls-Transvaal Power Company

132 kv, 444 mile-years of double circuit

$x/h = 0.12$, $y/h = 0.15$, protective angle = 40 degrees

The lightning and insulator subcommittee of the AIEE power transmission and distribution committee under the chairmanship of Philip Sporn submitted a report[23] in 1938 relating to the lightning performance of lines between 110 kv and 165 kv. A number of the lines tabulated in that report were selected for which the average tower-footing resistance was less than ten ohms. Figure 26 shows the outage data of these lines plotted against their protective angles. Some of the towers in this group must have had a footing resistance considerably in excess of 10 ohms which might explain some of the outages. In drawing this curve weight was given to the points which represented the largest circuit-years of experience. Information to plot the point marked by an x was furnished by W. Cronin, for the system of the Indianapolis Power and Light Company. The maximum tower-footing resistance for this system is 11 ohms. The curve indicates that satisfactory shielding is obtained for angles less than about 35 degrees. If an allowance of 10 or 20 degrees were provided for soil resistivity, lowering of effective ground plane across canyons and swinging of ground wires and phase conductors, a substantial check with laboratory results would be indicated.

Résumé and Conclusion

The relative development of the leaders preceding the actual discharge of the lightning stroke is the most important part of the mechanism which must be correctly simulated in model work when studying the shielding problem. In this regard natural lightning, both from positive and negative charge sources, is most closely simulated in the laboratory by making a point electrode positive with respect to a plane upon which is located the model transmission line to be tested. Positive-polarity discharges in the laboratory are more consistent in reproducing the same distribution curves and in obeying the laws of geometric similitude and also are less affected by weather conditions.

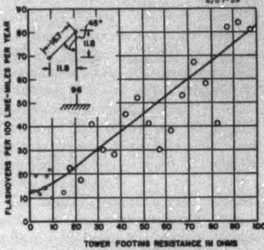

Figure 25. Lightning flashover record of lines of American Gas and Electric Company

132 kv, 2,426 mile-years of double circuit $x/h = 0.12$, $y/h = 0.12$, protective angle = 45 degrees

The results of model tests indicate that to limit the strokes to one per cent of the strokes to the line for a cloud height of ten times the ground wire height a protective angle of 50 degrees is necessary for y/h equal to 0.1 and 60 degrees for y/h equal to 0.2. These values have been checked substantially by operating experience upon lines in level country. Other factors enter the problem, chief of which are:

1. Cloud height. Strokes to the protected conductor decrease with increasing H in the manner shown in figure 16.
2. Soil resistivity and topography between spans. The effect of high soil resistivity is to lower the effective ground plane. A depression between spans such as a canyon or valley has a similar effect. In lowering the effective plane both y/h and H/h decrease which tend to increase the outages.
3. Transverse contour. The slope of the surface of the earth perpendicular to the transmission decreases the effective protective angle by the angle of the slope.
4. Wind. The relative deflection of ground wires and phase conductors under the wind conditions prevailing at the time of a storm may produce a very significant increase in the protective angle.

If a 20-degree tolerance is allowed for such uncertain factors as the above, a recommended value of protective angle at the tower of 30 degrees is obtained. This should prove adequate for all practical values of y/h.

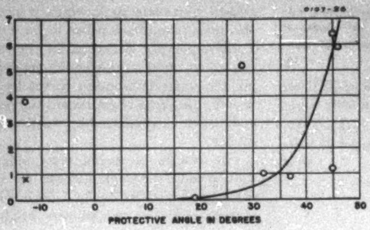

Figure 26. Lightning outage record as a function of protective angle for a number of lines whose average tower-footing resistance is less than ten ohms

Supporting data are given in the tabulation below

Lines	Mile-Years of Records	Average Resistance	Protective Angle	y/h	Distance Between Ground Wire and Conductor at Zero Swing	Outages Per 100 Miles Per Year

Appendix

Assume a flat earth surface of infinite extent and a uniform stroke density. If D represents the density of strokes per square mile per year, then from figure 5*b* it can be seen that the strokes that emanate from an element of cloud, dA in width and one mile in length is DdA. However, if A is measured in feet, this quantity becomes $D/5{,}280\ dA$, or $Dh/5{,}280\ d(A/h)$, where h is in feet. If n represents the fraction (not the percentage) of total strokes, as obtained from a distribution curve for a particular configuration and cloud height, that strike both conductors and ground wires, then the total strokes from element dA which strike the line is $Dh/5{,}280$ or $d(A/h)$. The total strokes to the line is then

$$S=\frac{Dh}{5{,}280}\int_{-}^{+} nd\left(\frac{A}{h}\right)$$

$$=\frac{2Dh}{5{,}280}\int_{-}^{+} nd\left(\frac{A}{h}\right)$$

Reduced to strokes per 100 miles this becomes

$$S=\frac{Dh}{26.4}\int_{0}^{+} nd\left(\frac{A}{h}\right)$$

The integral is simply the area under the distribution upon one side of the line.

Abnormal Voltage Conditions in Three-Phase Systems Produced by Single-Phase Switching

IT has been recognized for some time that in three-phase circuits, high voltages may cause damage to equipment following the blowing of a fuse or the nonsimultaneous opening or closing of switch contacts.[1–5] Motors on such circuits may reverse their direction of rotation. Field observations of the reversal of direction of rotation of motors have been reproduced in the laboratory, and the results reported.[6] Failures of lightning arresters, under conditions involving blowing of fuses or the opening of switches, appear to have occurred because of high sustained fundamental - frequency overvoltages above the arrester ratings. Cases of the breakage of a line conductor with resulting abnormal voltages have been noted. Abnormal voltage conditions have been observed on potential transformers.[7] The V.D.E. Standard,[8] in effect since October 1, 1925, points out the danger of using fuses and single-pole disconnecting switches under certain conditions, and states that the breakage of a conductor, where the end on the system side falls to ground, may give sustained voltages to ground on the portion of the conductor severed from the main system as high as $3\sqrt{3}$ times normal line-to-neutral voltage.

With the renewed interest in fuses at high voltages, and the possibility of using single-pole switches, the problem of determining the conditions under which these devices may be safely used in circuits supplying ungrounded transformer banks has attained new importance. This paper gives the results of an investigation to determine the conditions under which high voltages may occur with one and two conductors open, with and without faults, and suggests rules for the application of fuses and single-pole switches. Interpreting this reference to single-pole switches very broadly, one may include any type of switching device, such as single-pole disconnecting switches, oil circuit reclosers, horn gap switches, oil circuit breakers, etc. The interval of time between the closing or opening of the first and last phases may vary widely depending upon the type of switching device and also upon the circuit being energized or de-energized. For example, in cases of fuse operation, one phase or two phases may be open for a relatively long time. On the other hand, in the case of an oil circuit breaker, the interval of time during which one contact would be closed and two opened, for example, would be very short. The time required for the transition to the condition of sustained voltages depends upon the circuit constants and the characteristics of the interrupting device. It may vary from a few cycles to a relatively long period of several seconds. The phenomena to be discussed in this paper may be associated with any interrupting device which has characteristics such that the interval of time between the opening or closing of the first and last phases is of sufficient length to permit the ultimate steady state voltage conditions to be attained.

The phenomena encountered may be summarized as follows: When one conductor of a three-phase circuit supplying an ungrounded, unloaded transformer bank is open, there is a path for currents from the closed conductors through the exciting impedance of the bank and the capacitance between conductors to the open conductor, and thence to ground through the capacitance-to-ground of the open conductor. There is a similar path with two conductors open. When the three-phase system is grounded, the path is completed through the system grounded neutrals; if ungrounded, through the capacitance-to-ground on the system side of the opening. With the inductive reactance of the transformer bank paralleled by capacitance between conductors in series with line capacitance to ground, high voltage to ground at the transformer bank terminal or terminals of the open phase or phases will result for certain ratios of the transformer exciting reactances to the line capacitive reactances. The capacitances of the transformer bank, bushings, and bus structure, with no intervening length of line, may be sufficient to produce high voltages on small banks, such as potential transformers. The magnitude of the overvoltage is a function of the ratio of the line capacitive reactance to the transformer magnetizing reactance; or, approximately, the length of line left connected between the break and the transformer for a given transformer kilovolt-ampere and circuit voltage. The higher the voltage and the smaller the transformer kilovolt-amperes, the more likely are high voltages to occur for a given line length.

The solidly grounded and isolated-neutral systems were studied in detail. Systems with neutrals grounded through resistance or through reactance (including the ground fault neutralizer) were not included as part of this investigation. Single-phase, and three-phase shell-type and core-type transformers, with different primary and secondary connections, and the effect of one and of two open conductors, with and without faults to ground, are included in the study.

Basis of Study

Since the highest voltages are apt to occur with the unloaded or lightly loaded transformer bank, the study was made with the bank unloaded. Voltage conditions were obtained with transformer banks made up of three single-phase units and with three-phase transformers of both the shell-type and core-type, the windings on the line side and also the secondaries being connected alternately in delta and wye for each case.

Figure 1*a* gives a one-line diagram of the system studied, which consists of a three-phase power source supplying a transmission circuit and transformer bank through fuses or single-pole switches. It will be assumed that the three-phase system is large relative to the kilovolt-ampere rating of the bank, and therefore can be represented by an equivalent generator with balanced line-to-line voltages and negligible positive- and negative-sequence impedances. If the system is grounded, the equivalent generator will also have balanced line-to-ground voltages and its zero-sequence impedance will be

2—Assumed curve having more saturation than curve 1. Used in making calculations to determine the effect of this factor

3—Miniature system three-phase core-type transformer—158 rms volts line to line normal wye—840 ohms per phase normal magnetizing impedance

4—Miniature system three-phase shell-type transformer—144 rms volts line to line normal wye—520 ohms per phase normal magnetizing impedance

5—Miniature system special transformers 110 rms volts normal—13,200 ohms normal magnetizing impedance. Single-phase transformers

negligible. Figure 1*b* gives the miniature system[8] equivalent circuit for figure 1*a*, with which the study was made. The impedance of the sine-wave generator is very low relative to the exciting reactance of the unloaded transformer bank and the line capacitive reactances used, so that balanced line-to-line voltages are applied to the circuit at $a'b'c'$ under all conditions. The system becomes a grounded one with balanced line-to-ground voltages when switch S_N is closed. Resistance and reactance are neglected in the transmission circuit since they are insignificant relative to the capacitive reactances for the lengths of line under discussion. C_1' and C_0' represent the positive and zero-sequence capacitances, respectively, on the system side of the fuses or single-pole switches; C_1 and C_0, the positive and zero-sequence capacitances of the circuit supplying the ungrounded, unloaded transformer bank on the transformer side, which in figure 1*b* is shown as wye connected on the line side and delta connected on the load side.

To obtain various degrees of saturation for the miniature system transformer banks, it was only necessary to vary the normal operating voltage level in the miniature system. In obtaining the results herein summarized, the miniature system single-phase transformers were operated at a normal voltage corresponding to the saturation curve shown by curve 1 of figure 2. Curve 2 of figure 2 gives a transformer saturation curve with a slightly higher degree of saturation than 1 of the miniature system. Curve 5, for the specially built miniature system transformers, gives an intermediate value of saturation and because of its higher impedance, made it possible to cover a greater range of system constants. These curves are thought to be fairly typical of power transformer saturation. The saturation curves of the three-phase core-type and shell-type transformers of the miniature system are given by curves 3 and 4, respectively, of figure 2. These units are reproductions to scale of typical power transformers. All saturation curves give the ratio of the applied sinusoidal rms voltage to the exciting rms current, with voltage and current expressed in terms of normal voltage and normal exciting current, respectively.

Cases Studied

I. POWER SOURCE GROUNDED—LOAD TRANSFORMERS UNGROUNDED

A. One phase open—no fault.

1. Single-phase load transformers.

(*a*). Delta-connected on line side, wye- or delta-connected on load side.

(*b*). Wye-connected on line side, delta-connected on load side.

(*c*). Wye-connected on line side, wye-connected on load side.

2. Three-phase load transformers.

(*a*). Delta-connected on line side, wye-connected on load side.

1. Core type.
2. Shell type.

(*b*). Wye-connected on line side, delta-connected on load side.

1. Core type.
2. Shell type.

B. Two phases open—no fault.

Same as for *A*.

II. POWER SOURCE UNGROUNDED—LOAD TRANSFORMERS UNGROUNDED

A. One phase open—no fault.

1. Single-phase load transformers.

(*a*). Delta-connected on line side, wye- or delta-connected on load side.

B. One conductor open—fault-to-ground on system side of open conductor.

1. Single-phase load transformers.

(*a*). Delta-connected on line side, wye- or delta-connected on load side.

(*b*). Wye-connected on line side, delta-connected on load side.

(*c*). Wye-connected on line side, wye-connected on load side.

C. One conductor open—line-to-ground fault on load side of open conductor.

1. Single-phase transformers.

(*a*). Delta-connected on line side, wye- or delta-connected on load side.

Results

Curves showing the voltages to ground of the open phase or phases as a function of the system constants were obtained from the miniature system by varying the capacitances, C_1 and C_0, but keeping their ratio constant. Data were obtained for $C_1=C_0$ and $C_1=2C_0$ for the solidly grounded system. Calculated curves were obtained by the methods given in the appendix.

In order to demonstrate the effect of various factors in producing overvoltages and phase reversal, case 1 will be discussed first in detail. Throughout the following discussion, x_m is the magnetizing reactance of the transformer bank on

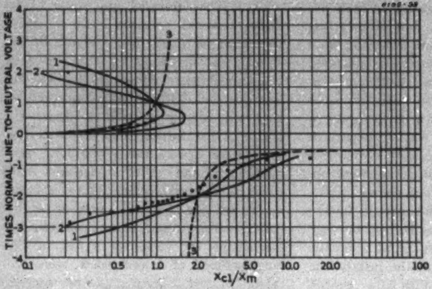

Figure 3a. Steady-state maximum voltages on open phase with one conductor open. No fault on system. Power source solidly grounded

the load side of the open conductor at normal voltage. In more general terms, it is the equivalent magnetizing reactance of the total transformer kilovolt-amperes on the load side of the fuse or single-pole switch location. Thus, the single-load transformer of figure 1*b* may be considered as the equivalent of several smaller transformers all on the load side of the open conductor. Likewise, the positive- and zero-sequence capacitive reactances, x_{c1} and x_{c0}, respectively, should be interpreted in a more general manner to correspond to total positive and zero-sequence capacitances C_1 and C_0 on the load side of the open conductor. Thus the results assume much broader significance and are much more widely applicable.

I. SOURCE GROUNDED—A. ONE PHASE OPEN—NO FAULT

1. *Single-Phase Transformers*

(*a*). *Delta-Connected on Line Side, Wye- or Delta-Connected on Load Side.* The curves of figure 3*a* give the steady-state maximum peak voltage of the open conductor on the transformer side of the opening in terms of normal line-to-neutral peak voltage with the transformer bank delta-connected on the line side, and wye- or delta-connected on the load side, versus x_{c1}/x_m for $C_0=C_1$. Curves 1, 2, and 3 are calculated by methods given in the appendix. Curve 1 gives calculated voltages using saturation curve 1 of figure 2, which corresponds to the saturation of the miniature transformers.

Curve 2—Saturation curve 2, figure 2

Curve 3—No saturation

Curve 4—Neutral displacement saturation curve 1, figure 2

Points obtained by test on the miniature system are indicated. The general shape of calculated and test curves is the same, although calculated voltages are higher except for large ratios of x_{c1}/x_m where both calculated and test voltages are less than normal.

The reference vector for calculated voltages is the voltage of the open phase on the system side of the opening, so that with no capacitance in the circuit, or $x_{c1}=\infty$, the voltage on the transformer side of the opening is -0.5 and the voltage at the load is single-phase. As the ratio x_{c1}/x_m is decreased, the voltage of the open phase increases in magnitude in the negative direction and there is phase reversal at the load. At $x_{c1}/x_m=2$ for all calculated curves and about 1.5 for the test curve, the voltage-to-ground of the open phase is -2 and the line-to-line voltages at the load are balanced normal voltages of reverse phase rotation. (For the calculated curves, $V_a=-2$, $V_b=-{}^1/_2-j\sqrt{3}/2$, $V_c=-{}^1/_2+j\sqrt{3}/2$). As x_{c1}/x_m is further decreased the voltage-to-ground of the open phase continues to increase and remains negative on both calculated and test curves; but before $x_{c1}/x_m=1$ is reached, two other steady-state values of voltage are possible as indicated by the calculated curve. Both are positive. Only one of these other indicated values was obtained in test, the lower of the two, until x_{c1}/x_m was decreased to about 0.2 but for values of $x_{c1}/x_m=0.2$ or lower, three different values were obtained by test. Figure 4 shows oscillograms of the voltages and currents for the three possible stable conditions, any one of which may occur, depending upon the phases of the voltages at the instant the switch is opened. With the switch opened at random a number of times, the high negative voltage or the low positive occurred more often than the medium positive voltage.

Curve 2 of figure 3*a* was calculated, using transformer saturation curve 2 of figure 2. Curve 3 is for no saturation.

Figure 3*b* is similar to figure 3*a* except that $C_1=2C_0$. The voltages above normal of figure 3*b* are lower than those of figure 3*a* for the same values of x_{c1}/x_m.

(*b*). *Wye-Connected on Line Side, Delta-Connected on Load Side,* (*c*) *Wye-Connected on Load Side.* Figure 3*c* for $C_1=C_0$ and figure 3*d* for $C_1=2C_0$, with the transformers wye-connected on the line side and delta- or wye-connected on the load side, are similar to figures 3*a* and *b*. Test values from the miniature system for $C_1=C_0$ and a wye-delta connection do not differ materially from those for the transformer delta-connected on the line side except that only two of the stable voltage conditions indicated by calculation for values of x_{c1}/x_m in the neighborhood of 1 and below, were obtained in test. Figure 5 shows oscillograms of the voltages for the two stable conditions obtained at $x_{c1}/x_m=0.15$, with $C_1=C_0$. No tests were made for $C_1=2C_0$.

2. *Three-Phase Transformers*

(*a*). *Delta-Connected on the Line Side, Wye-Connected on the Load Side.* Figure 6*a* gives test values of the voltage-to-ground of the open phase for both core-type and shell-type transformers, delta-connected on the line side and wye-con-

nected on the load side, obtained from the miniature system with saturation curves 3 and 4, respectively, of figure 2 and with $C_1 = C_0$. Calculated values of voltage for saturation curves 3 and 4 of figure 2 are not given, but they would not differ materially from those for saturation curve 1 of figure 2, given by curve 1 of figure 3*a*. In general, the curves of 6*a* agree with those of 3*a*, except that the medium voltage of the three calculated voltage conditions indicated by calculations for values of x_{c1}/x_m in the neighborhood of 1 and below, does not appear. Instead, for x_{c1}/x_m lower than 0.7, higher voltages than indicated by calculations appear, giving three stable voltage conditions. These high voltages have pronounced subharmonics[10,11] and therefore could not be predicted by the methods used. However, they are but little higher than the calculated voltages of curve 1, figure 3*a*.

(*b*). *Wye-Connected on Line Side, Delta-Connected on the Load Side.* Figures 6*b* for $C_1 = C_0$ and 6*c* for $C_1 = 2C_0$ are similar to figure 6*a* except that the transformers are wye-connected on the line side and delta-connected on the load side. Only two stable voltage conditions were obtained for values of x_{c1}/x_m in the vicinity of 1 and below. The voltages of figure 6*b* are substantially the same as those of figure 3*c* for the same values of x_{c1}/x_m.

B. Two Phases Open—No Fault

While numerous factors were investigated in connection with this condition as outlined in the summary of cases studied, detailed results will not be shown. Instead, a composite curve showing the range of values obtained for all of the conditions studied using single-phase transformers is shown in figure 7. The narrow range of values obtained indicates that the transformer connection and its construction (core, shell, or single phase) have little effect on the overvoltages obtained. Figure 8 shows some typical oscillograms for one case with single-phase transformers.

II. Power Source Ungrounded—Load Transformers Ungrounded—

A. One Phase Open—No Fault

1. *Single-Phase Transformers—(a) Delta-Connected on the Line Side, Wye- or Delta-Connected on the Load Side*

Figure 9 gives the calculated voltages-to-ground of the open phase on the load side of the opening in per unit of normal peak line-to-neutral voltage, with x_{c1}/x_m as abscissa and x_{c0}'/x_{c1} as parameter, for $C_1 = C_0$, and the voltage of the open conductor on the system side as reference vector. Test points from the miniature system with saturation curve 1 of figure 2 for various values of x_{c0}'/x_{c1} are indicated. The voltages are independent of x_{c1}'.

B. One Conductor Open—Fault-to-Ground on the System Side of the Open Conductor—Single-Phase Transformers

Figure 10 shows the range of voltages obtained for the various transformer connections. Here again the transformer connections make little difference except for very low ratios of x_{c1}/x_m. The wye-delta connection tends to reduce the overvoltages somewhat in this region.

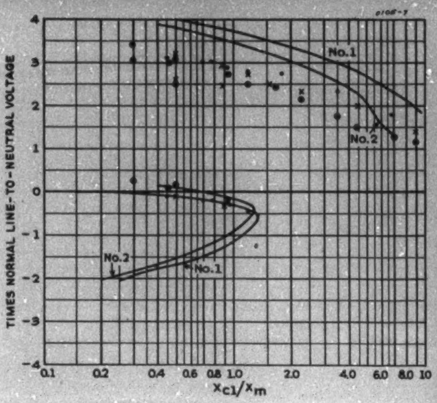

Figure 7. Steady-state voltages on open phase with two conductors open. No fault on system. Power source solidly grounded

Curve 1—Calculated using curve 1, figure 2 for $C_1 = C_0$ and transformers delta-connected on line side and wye-connected on load side

Curve 2—Same but $C_1 = 2C_0$

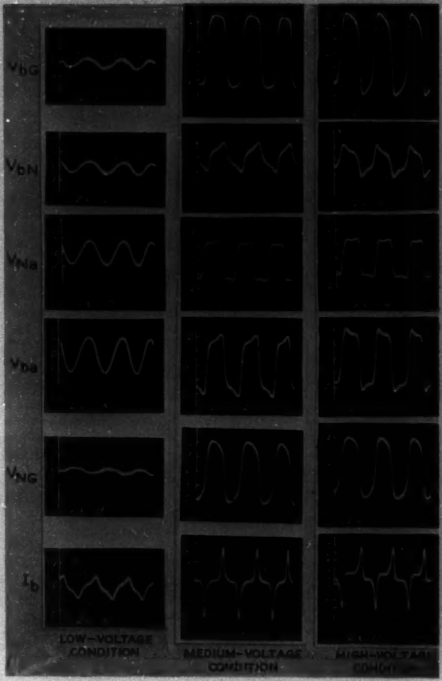

Figure 8 (right). Wye-connected load transformer, $C_0 = C_1$, $x_{c1}/x_m = 0.89$. Phases b and c open

Calibrations: Current—Times normal crest transformer exciting current. Voltage—Times normal line-to-neutral crest voltage

C. One Conductor Open—Line-to-Ground Fault on the Load Side of the Open Conductor—Single-Phase Transformers Delta-Connected on Line Side—Wye- or Delta-Connected on Load Side

Figure 11 shows the voltages obtained for this assumed condition. It should be noted that the severity of this system from the standpoint of overvoltages can be defined for all practical purposes by the ratio of total zero-sequence capacitive reactance to transformer magnetizing reactance. The ratio of $x_{c0'}/x_{c0}$ has relatively little effect.

The basic circuit which produces the high voltages shown for this condition is somewhat more complicated than those circuits investigated in the other cases. The principal elements of the circuit are a capacitance in series with a parallel circuit composed of another capacitance and a saturable reactance. These three elements can be identified with the zero-sequence capacitance on the system side of the open conductor, a parallel combination of system and load-side zero-sequence capacitances, and the magnetizing reactance of the transformer respectively shown in figure 1*b*.

If the total capacitive reactance of the system (capacitance on both sides of the opening) is large, no high voltages are produced. As this reactance is decreased, voltages are increased. Only one voltage value is obtained until the ratio of total zero sequence system capacitive reactance to magnetizing reactance, $x_{(c0+c0')}/x_m$, reaches a value of about 5.0. Below this value, three stable voltage conditions were obtained in some cases. As the capacitive reactance was decreased, increasingly higher maximum voltages were obtained. With a relatively low-loss transformer (curve 1 of figure 2), the high-voltage condition could be obtained for values of $x_{(c0+c0')}/x_m$ down to 0.03, although the low-voltage condition occurred more often. In other words, the higher the voltage, the less would be the probability of reaching that voltage.

With the smaller transformers (curve 5 of figure 2) which had slightly higher losses, the high-voltage condition did not occur for values of $x_{(c0+c0')}/x_m$ below 0.2, approximately. This elimination refers only to the steady-state condition, however. In many cases, long transient conditions were observed, which could be quite hazardous to insulation or connected apparatus. It is important to bear this in mind in connection with the protective criterion offered in the latter part of this paper.

Figure 11 indicates that phenomena such as this can take place in a relatively large percentage of ungrounded systems. Perhaps the occurrence of faults followed by the blowing of fuses may account for much of the heretofore obscure transient phenomena occurring in isolated-neutral systems.

Discussion

The manner of connecting the windings of an ungrounded transformer bank, whether delta-delta, delta-wye, wye-wye, or wye-delta, does not materially affect the magnitudes of the voltages-to-ground obtained on the open phases except in the very high voltage region. The voltages-to-ground of the open phases obtained with three-phase transformers of both core-type and shell-type are approximately the same as those obtained with banks of single-phase units, with the same saturation curve, for corresponding values of x_{c1}/x_m.

The method of calculating sustained voltages-to-ground when one or two conductors of the three-phase circuit supplying an unloaded, ungrounded transformer bank are open, gives values which approximately check tests made on the miniature system. Except where the calculated voltages are less than normal, the method gives values, which, with a few exceptions in the very high voltage region, are too high. The method can therefore be considered to give conservative values.

While test points agree quite well with calculated results, it may be well to point out that for some of the conditions which gave rise to very high voltages, it was possible to obtain slight variations in the wave shape depending upon the initiating conditions. For instance, the high voltage might, for one opening of the switch, be essentially of fundamental frequency. For a second opening of the switch, it might be essentially of the same magnitude, but contain definite subharmonics.[10,11] Some of these subharmonics observed were of very low frequency.

For the ground system or the isolated system effectively grounded through its capacitance to ground, a fault to ground on the open conductor, or conductors, on the system side of the opening, or openings, does not affect the sustained voltages at the transformer bank terminals. A fault-to-ground on the transformer side of the opening reduces the voltage there to zero. The highest voltages are obtained when two conductors are open and there is no fault. Such a condition can exist when a line-to-line fault is cleared by the blowing of two fuses; and also on a circuit controlled by single-pole switches when one phase is closed before the other two.

If the peak value of the sustained voltage-to-ground of the open conductor on the load side of the opening in a solidly grounded system with ungrounded transformer bank is to be kept below 1.73 times normal line-to-neutral peak voltage, the approximate length of line, *l*, between the opening and the transformer bank should not exceed a value which can be approximately determined from the normal voltage of the line and the rated kilovolt-amperes and exciting current of the transformers.

The positive-sequence capacity susceptance of overhead transmission circuits, $2\pi fC_1$, in micromhos per mile at 60 cycles varies from about 5 to 7, depending upon the diameter of the conductors and the spacing between them. Since these, in turn, depend upon voltage, $2\pi fC_1$ at a given voltage and frequency can be estimated with fair accuracy. The following values will be taken as typical at 60 cycles:

Kv	$2\pi fC_1$ Micromhos Per Mile
230–115	5.2
69–34.5	5.5
34.5–13.8	6
Below 13.8	6.5

The zero-sequence capacitance of overhead transmission circuits is less than the positive, but usually greater than one-half the positive.

From figure 7 it is seen that calculated voltages in the region of 1.73 times normal line-to-neutral voltage are greater than test voltages. Allowing for this, and with $C_1 > C_0 > C_1/2$, voltages above 1.73 times normal will probably not occur with transformers of the usual degree of saturation if the ratio x_{c1}/x_m is 6 or greater.

With a criterion of $x_{c1}/x_m = 6$,

$$x_{c1}/x_m = I_m x_{c1} = I_m \frac{10^6}{2\pi fC_1 l} \times \frac{\text{kva}}{\text{kv}^2 10^3} = 6$$

$$\therefore l = I_m \frac{\text{kva } 10^3}{\text{kv}^2} / 6(2\pi fC_1) \qquad (1)$$

where

l = allowable length of line between fuses or single-pole switches and load transformer bank

kva = rated kilovolt-amperes of the transformer bank

kv = normal line-to-line voltage of the circuit in kilovolts

I_m = average per unit rms exciting current at normal voltage

$2\pi f C_1$ = positive-sequence capacitive susceptance of the circuit in micromhos per mile

The transformer exciting current I_m lies between 1 per cent and 7 per cent, with 3.5 per cent not an unusual value. Figure 12, drawn with $I_m = 3.5$ per cent, gives the approximate maximum allowable length of line at various voltages supplying a transformer bank of given kilovolt-ampere rating and 3.5 per cent average rms magnetizing current which can be operated by fuses or single-pole switches without the risk of voltages-to-ground exceeding line-to-line voltages when two conductors are open. This allowable length of line varies directly as the per unit rms exciting current of the bank and inversely as the ratio x_{c1}/x_m selected. For an rms exciting current of 7 per cent, the allowable lengths of line would be doubled; for an exciting current of 1 per cent, they would be only about one-third those of figure 12.

Since for some cases, the maximum allowable length of line is very short, it may be necessary under such conditions to take into account the internal capacitance of the transformer bank itself. Generally this will not have to be done. For cases requiring this refinement, representative values of internal capacitance of power transformers are given in a convenient form by L. V. Bewley.[12] In figure 8 of his paper he gives the capacitance between windings in magnetomotive force per phase which may be considered as the capacitance to ground, as the capacitance of the low-voltage winding to ground is usually larger, while the capacitance of the high-voltage winding to ground is small. The largest values of capacitance given are on the order of 0.01 microfarad which would be equivalent to one mile of line, or less under most conditions. For the higher voltages, the internal capacitance would be equivalent to considerably less than a mile of overhead line. Bushing capacitance, being very small relatively, can be neglected.

In case the transmission circuit contains some cable, its equivalent in terms of miles of overhead line may be used. For that purpose, figure 13 has been prepared which makes it possible to evaluate this equivalent readily. This figure has been reproduced from reference 13.

For the ungrounded system, it is important to note that the criterion for the solidly grounded system is adequately conservative for conditions not involving faults. See figure 9. However, should a permanent fault occur on the system side, the criterion must be changed if voltages are to be limited to maximum values of $\sqrt{3}$ times normal. Figure 10 shows that a minimum ratio of $x_{c1}/x_m = 25.0$ approximately is required. This criterion alone is not sufficient, however. If a permanent fault on the load side is assumed, then the total zero sequence capacitance of the system must be very large or else very small in order to prevent overvoltages. See figure 11. Therefore, in addition to imposing the criterion of $x_{c1}/x_m \geq 25.0$, restrictions must also be imposed on the ratio of $x_{c0'}/x_m$.

From figure 11, the ratio of $x_{(c0+c0')}/x_m$ should be less than approximately 0.04 or greater than a value varying from 4.7 to 25.0 approximately, depending upon the ratio $x_{c0'}/x_{c0}$. In the light of our first restriction on x_{c1}/x_m, this can be conservatively interpreted to impose the restriction that $x_{c0'}/x_m$ must be less than 0.04 or greater than 40.0 approximately.

Figure 12 can be used to interpret the first criterion in terms of total transformer kilovolt-amperes, system voltage, and maximum allowable lengths of line on the transformer side of the open conductor location. This figure is based on a ratio of $x_{c1}/x_m = 6.0$ and since for the isolated system this must be increased to approximately 25.0, it is necessary to divide the miles of line shown by approximately 4.0 in order to conform to the required criterion.

In figure 14 the second criterion, imposing the restrictions on the lengths of line on the system side of the open conductor, is shown. This curve shows that overvoltages may be expected as a result of faults and subsequent fuse blowing for wide ranges of system constants.

In applying these criteria, it should be pointed out that these are approximate values. In some cases it may be necessary to make a more detailed calculation. Exact line configuration, exact magnetizing reactance, and more detailed knowledge concerning the particular transformer saturation characteristics may be necessary. However, the curves serve to indicate in general the range of system constants which can give rise to high

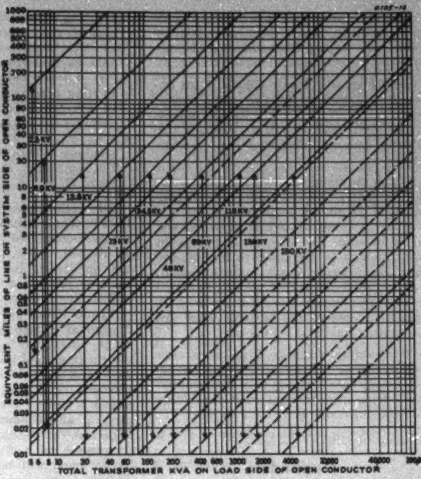

Figure 14. Isolated neutral system—approximate range of equivalent line lengths on system side of fuse or single-pole switch location which may cause voltages greater than $\sqrt{3}$ times normal with one conductor open and a single line-to-ground fault on the load side

x_{c0}'/x_m must be greater than 40.0 or less than 0.04

I_m=3.5 per cent rms average exciting current

NOTE: Allowable length of line varies directly with rms average exciting current

NOTE: This criterion alone is not sufficient for elimination of overvoltages. The criterion of figure 12 must be met also. Maximum permissible miles of line in figure 12 should be divided by 4.0 for the isolated-neutral system

overvoltages in isolated-neutral systems. Under lightly loaded conditions, it would seem that a relatively high percentage of isolated-neutral systems are subject to overvoltages as a result of fuse blowing or single-pole switching under permanent fault conditions.

Obviously, there are other combinations of faults and open conductors possible in isolated systems which might tend to shift somewhat the range of constants causing high voltages. In distribution circuits involving single-phase feeders, a single blown fuse can sometimes cause overvoltages if the system constants are of certain values. Generally, such cases can be interpreted in terms of three-phase constants such that some one of the numerous curves included in this paper can be used directly in determining the overvoltages possible.

The effect of load on the transformers is to reduce the voltages on the open phases obtained with the transformers unloaded. With the transformers loaded and phase a open, V_a, the voltage of the open phase on the transformer side of the opening referred to the voltage on the system side, will have a quadrature component in addition to the positive or negative in-phase component. If the in-phase component is negative and greater than -0.5, V_{a2} will be greater than V_{a1} and there will be phase reversal. Running motors, however, will not slow down if the difference between the positive- and negative-sequence torques is equal to that required to maintain rotation in the positive direction, but if it is less, they will slow down and stop. They will then reverse their direction of rotation if the negative sequence torque is great enough to overcome the positive sequence torque and provide the torque required to start the motors from rest. With a motor running, the positive sequence torque is greater than the negative for equal positive and negative sequence voltages. At standstill, these torques are equal for equal voltages.
